Separation of Toluoline and Pseudo-Toluoline.—Dr. Bindschedler, of Basle.—Dalsace Bros., of Paris, sell a special heavy aniline, boiling between 198° and 20° , and containing little except toluoline and pseudo-tolui. In acetylising this heavy aniline it was found to yield solid and crystallisable aceto-toluidine, corresponding in amount to a mixture of 70 per cent pseudo-toluidine, with 30 of crystallisable toluoline. The following process may be adopted for the isolation of pure pseudo-toluidine:—Dissolve 2500 grms. of oxalic acid in 25 litres of boiling water, adding afterwards 6 litres of commercial hydro-

chloric acid at 20°B . Into this mixture 10 kilos. of the heavy aniline are slowly poured. The whole is boiled up again, and constantly stirred whilst it cools down to 60°C . It is then rapidly filtered through flannel to separate the crystalline deposit. This is pressed, ground up with a little cold water, and pressed again. On decomposing it with caustic soda and distilling, crystalline toluoline is obtained, fusing at 450°C . To the filtrate we add, with constant stirring, 2 kilos. of oxalic acid, which determines a further crystalline deposit. This consists of a mixture of oxalates of toluoline and pseudo-toluidine, which, from its richness in the former, serves to prepare a further quantity of that base. The mother-liquors from this second crystallisation, completely cooled after filtration, are tested with a concentrated aqueous solution of oxalic acid. The mixture is strongly agitated, and if no further crystalline deposit is formed (in which case it must be filtered again) an excess of caustic soda is added, and the whole submitted to distillation. The oily layer which floats on the condensed water is drawn off, rectified, and is a pseudo-toluidine sufficiently pure for all industrial uses, as it contains mere traces of aniline and toluoline.

Revue Scientifique de la France et de l'Etranger, No. 45, May 10, and No. 46, May 17, 1873.

These numbers contains no chemical papers.

Gazzetta Chimica Italiana, Anno III. 1873, Fascicolo III.

On Certain Derivatives of Benzylated Phenol.—E. Paterno and M. Fileti.—The action of the chloride of acetyl and of sulphuric acid upon benzylated phenol is particularly studied.

Examination of the Scientific Principles of the Art of Dressing Hides.—A. Reimer.—In this memoir the author examines the action of pure water, of lime-water and other alkaline liquids, of potash-alum, and of common salt.

Refractive Power of Saline Solutions and its Modifications.—C. A. Valson.

Fascicolo IV.

On Certain Properties of Gypsum.—Alfonso Cussa.—The author studies the solvent action which gypsiferous waters exert upon different rocks.

On the Apparent Variability of the Law of Dulong and Petit.—G. Hirn.—A physico-mathematical paper.

Experiments on the Cultivation of the Sugar-Beet, made in the Year 1872, at Grotta Rossa, in the Campagna of Rome.—F. Sestini and G. Del Torre.

Experiments on Vinification by the Method of Chaptal.—L. Moschini and F. Sestini.—This process consists in the addition of a certain quantity of powdered marble during fermentation. The results appear to have been—an increase of alcohol, amounting in one instance to more than 2 per cent; a decrease of extractive matter; a decrease in phosphoric and sulphuric acids, and in chlorine.

Les Mondes, Revue Hebdomadaire des Sciences, par L'Abbé Moigno, Tome xxxi., No. 3, May 15, 1873.

Diamonds in the Sands of California.—Professor Silliman having received from Mr. Trendwell, of San Francisco, a small parcel of the sand resulting from the hydraulic treatment of ores, found, on examination with the microscope, that they abounded in fine colourless zircons of the form of those of Expailly, along with crystals of topaz, fragments of quartz, grains of chromic acid (chrome-iron?) and titanite acid, and globular bodies of a very high refractive power, which he believes to be diamonds. Mr. J. Torrey, in a single sample of the sands washed from the gold ores of Nicaragua, found twenty mineral species, some of them very rare.

No. 4, May 22, 1873.

Distillation by Cold.—At a recent session of the Berlin Chemical Society Prof. Smée proposed a method for detecting organic matters contained in the air, and for effecting at the same time a kind of distillation by cold. A glass funnel, closed at its narrow end, is held suspended in the air and filled with ice. The moisture of the air is condensed in contact with the exterior surface; it trickles to the bottom of the apparatus, and falls into a small basin placed for its reception. The liquid obtained in a given time is weighed. It generally contains ammonia, which is determined by known methods. Distillation by cold may be employed for separating volatile substances which might be injured by heat. Thus if flowers are placed under a large bell-glass along with the refrigerating funnel, a liquid is obtained in the basin saturated with the odorous principles of the flowers.

Journal für Gasbeleuchtung und Wasserversorgung,

These only contain papers relating to gas- and water-works engineering and management.

No. 5.

Sal-Ammoniac in the Hydraulic Main.—R. Gasch. —While the hydraulic main of the gas-works at Dresden was being cleaned a large quantity of a whitish-coloured saline mass was met with, mixed up with the inspissated tar. At first this saline matter was taken to be bicarbonate of ammonia, but on being chemically tested the salt was found to be chloride of ammonium. The author found that the salt is derived from the Zwickau coals, which (see CHEMICAL NEWS, vol. xxvi., p. 226) contain a considerable quantity of common salt. Sal-ammoniac is now a regular by-product of the Dresden gas-works.

Nos. 6 and 7.

These only contain matter relating to gas- and water-works engineering and management.

Bayerisches Industrie und Gewerbe-Blatt, February, 1873.

Soldering of Iron and Steel.—Ph. Rast. —So-called German silver may be applied to soldering steel to iron and iron to copper. Borax should be used as a flux, and the German silver granulated as is done for hard brass solder.

Gilding of Iron.—W. Kirchmann. —Sodium amalgam is first applied to the iron, which is hereby readily coated with mercury. Next a concentrated solution of chloride of gold is applied to the mercurially coated surface; and lastly, the object is strongly heated, either in a muffle or in the flame of an enameller's lamp.

March and April.

These contain no articles relating to chemistry.

Annalen der Physik und Chemie, von Dr. J. C. Poggen-dorff, No. 3, 1873.

Solubility of Saline Mixtures.—F. Rüdorff. —In the introduction to this first portion of an exhaustive monograph a *résumé* is given of the labours of Gay-Lussac, H. Kopp, C. J. B. Karsten, G. J. Mulder, and C. v. Hauer, on this subject: The author then treats on the solubility of saline mixtures—(1), of such salts with which a chemical decomposition cannot take place, salts containing either the same base or the same acid; (2), saline mixtures which admit of double decomposition, salts therefore containing either two bases or two acids.

Bulletin de l'Académie Royale de Belgique, No. 1, 1873.

Note on Shifting Instantaneous Axes and Central Axes in a Solid Body in Motion.—M. de Tilly. —These notions, which in most treatises on kinematics, are preceded by a large number of preliminary pro-

positions, the author seeks to establish in a more simple, *a priori* manner.

Note on a Singular Configuration of Spots on the Planet Mars, observed by P. Secchi on 18th Oct., 1862.—Dr. F. Terby. —In comparing P. Secchi's drawing of the appearance of Mars on that occasion with those by Mr. Lockyer, from observation made only 36 minutes later, Dr. Terby remarks on the round dark spot with luminous ring, represented in the former only, and which Secchi supposed to be from a cyclonic movement on the ocean of De La Rue. It has been thought that a shaded part extending outwards from beyond the ring, in Secchi's drawing, corresponded to the sea of Lockyer. But Dr. Terby gives reasons for considering Secchi's round spot itself as the sea of Lockyer, while the other just mentioned is more likely the sea of Maraloi, appearing also also in Lockyer's drawings. Dr. Lassell's and Lord Rosse's drawings give certain details which vaguely recall the drawing by P. Secchi, the sea of Lockyer being surrounded by a luminous ring.

No. 2.

This number contains no articles which call for notice.

No. 3.

On Man considered in the Social System either as a Unit, or as a Fragment of the Human Species.—M. Ad. Quetelet. —The author explains the general nature of his researches towards construction of a system of "Social Physics." In a table at the end he furnishes statistics of chest measurements on about 1,500 American soldiers, and compares these with measurements obtained by calculation from certain data; finding a close correspondence.

Researches on the Etherised Derivation of Alcohols on Acids (On Methylenic Mono-Cyanhydride, $\text{HOCH}_2 + \text{CN}$). —The author suggests that this product might be obtained by the reaction of anhydrous hydrocyanic acid on the formic aldehyde, or oxide of methylene, CH_2O . Not having been able to attempt this, he sought to fill the gap in the group of methylenic and glycollic derivatives by realising one of the corresponding alcoholic derivatives $(\text{C}_n\text{H}_{2n+1}\text{O})\text{CH}_2 + \text{CN}$; and with this view he produced *ethyl-glycollic nitrile*, $(\text{C}_2\text{H}_5\text{O})\text{CH}_2 + \text{CN}$; by reaction of phosphoric anhydride or pentachloride of phosphorus with ethyl-glycollamide—
 $(\text{C}_2\text{H}_5\text{O})\text{CH}_2 + \text{COH}_2\text{N}$.

It is a mobile colourless liquid, with an agreeable ethery odour; density at $+5^\circ$ is 0.915; boiling-point, at atmospheric pressure, 134° — 135° . In this product he finds an illustration of the remarkable stability of oxyalcoholic combinations, methoxyle, CH_3O , ethoxyle, $\text{C}_2\text{H}_5\text{O}$, &c.; with regard to agents, such as chlorides, bromides, &c. of phosphorus, phosphoric anhydride, &c., which so readily attack the equivalent and corresponding hydroxyle grouping HO . He gives several examples of transformations and combinations he had succeeded in realising with these polyatomic compounds, by virtue of this property.

Annales de Chimie et de Physique, April, 1873.

Nitrification of Humus.—J. Boussingault. —The author calls attention to the spontaneous formation of saltpetre in many parts of Algeria, Spain, Hindostan, South America, and other localities. The chief portion of this memoir is, however, devoted to the discussion of the origin and mode of formation of the saltpetre in arable soil, and more particularly in soil containing decaying organic matter. From the author's researches, it appears that (1) the nitrification, even under the most favourable conditions, is a slow process; (2) that in the nitrification of humus, when proceeding in a confined space (under a bell-jar, for instance), the nitrogen of the air does not contribute to the formation of nitric acid; (3) that, as a

rule, the process depends upon the organic matter present in the humus, and in all fertile soil, but is promoted by the presence of certain bases.

Studies on Valerianic Acid.—I. Pierre and E. Puchot. —The contents of this memoir may be summarised as follows:—Valerianic acid, obtained by the oxidation of amylic alcohol, and concentrated, boils at 178° . At 760 m.m. barom. the sp. gr. of this acid is—at $0^{\circ}=0.947$; at $54.65^{\circ}=0.8972$; at $99.9^{\circ}=0.8542$; at $147.5^{\circ}=0.8095$. The acid contains 1 equivalent of water, which cannot be eliminated by distillation. Mixed with an excess of water, the acid boils at from 99.8° to 100° , and the condensed vapours form two distinct layers of liquid, one of which is an aqueous solution of the acid, while the upper layer is the hydrated acid. Valerianic acid causes the same deviation of the plane of polarisation as does cane sugar. Butyric valerianate exhibits the same phenomenon, but in a less marked degree.

Researches on the Expansion and Compressibility of Gases.—E. H. Amagat. —Illustrated by woodcuts and tables. The main results of the exhaustive researches herein described are:—(1) Unless gases are well dried, their expansion is (the vessels in which the operations take place being quite dry) not so great as has hitherto been assumed; (2) the differences of the coefficients of the expansion of gases is not, as has been sometimes stated, due simply to moisture; (3) it is impossible to base a hygrometric method on part which the moisture of the air plays in its expansion, because, even when the hygrometric condition of the air differs greatly, the variation of the coefficient is difficultly appreciable.

Polytechnisches Journal von Dr. E. M. Dingler, first number for March, 1873.

Application of Titration for the purpose of Estimating the Degree of Alkalinity of Beet-root Juices used in Sugar-Making.—F. Jicinsky. —Nitric acid (sp. gr. 1.2), diluted with 150 times its bulk of pure distilled water, is taken as the standard acid. 1 c.c. of this acid corresponds, by the application to 10 c.c. of juice, to 0.01 per cent of alkalinity in reference to lime. The author describes, and illustrates by woodcuts, the apparatus employed by him for the titration operation. Litmus tincture also is used to indicate the progress of the operation.

Volumetric Estimation of Sugar.—F. Weil. —A previously-weighed or measured quantity of a solution of grape sugar, or of cane sugar first converted into grape sugar, is added to a measured quantity of Fehling's sugar-testing cupreous fluid (to be used in excess, so that after the operation the blue colour yet prevails); the precipitated copper is removed from the solution by decantation, and the quantity of that metal determined by analysis, care being taken to ascertain the total quantity of copper present in the solution. 317 grms. of copper correspond exactly to 180 grms. of grape sugar ($C_{12}H_{22}O_{11}$), or to 171 grms. of cane sugar ($C_{12}H_{22}O_{11}$).

Preparation of Pure Oxalic Acid.—Dr. Habedonck. —The oxalic acid of commerce is treated with the smallest possible quantity of absolute alcohol, which only dissolves the real acid, leaving oxalates of lime, potassa, ammonia on the filter, through which the alcoholic solution passes. The acid crystallises from the alcoholic solution, and is dried at 212° to eliminate any oxalic ether which might have been formed.

Second number for March, 1873.

Contains no original papers relating to chemistry.

First number for April, 1873.

Curious Instance of the Rapid Diffusion of Specifically Lighter Gas Layers through Layers of a Specifically Heavier Gas.—Dr. M. von Pettenkofer. —In the introduction to this essay the author calls attention

to the erroneous ideas on the diffusion of gases and on the proper modes of ventilation. As a curious instance of the rapidity, as well as the completeness, of diffusion, the author relates some experiments made by him at Marienbad, Bohemia, on the mineral spring there situated, from which constantly a copious supply of nearly pure carbonic acid is emitted. The gas collected under the surface of the water was found to contain 70 per cent of carbonic acid; at 5 centims. above the surface of the water there was only 31 per cent of that gas; at 25 centims. above the surface the quantity of CO_2 amounted only to 23 per cent; at 100 centims. only 2, and at 145 centims. only $\frac{1}{4}$ per cent of the gas alluded to was found; thus proving that the lighter air (the spring is enclosed in a lightly-constructed wooden shed) actually descends and permeates through the heavier carbonic acid.

Detection of Adulteration in Coffee.—J. Müller. —In order to ascertain whether ground coffee has been mixed with either roasted corn or amylaceous substances generally, it is only necessary to treat the powder, first with dilute caustic potassa, and, after filtration and addition of a large quantity of pure water, a solution of iodine is added, whereby the starch is detected.

Second number for April, 1873.

Change Effected in Cast-Iron Pipes by the Action of a Sulphur-containing Water.—Dr. E. Priwoznik. —It appears that, when the iron mains conveying the mineral water from a source near Hainburg, Austria, were taken up after having been for more than a dozen years underground, the iron thereof had been strongly acted upon, as exhibited by the difference in structure upon the fracture. On being analysed, the author found the interior layer to consist, in 100 parts, of—Hydrated oxide of iron $[(Fe_2)_2O_3(OH)_6]$, 81.08; free sulphur, 12.29; sulphuret of iron, 4.48; hygroscopic water, 0.57; nickel, cobalt, magnesia, silica, traces of carbon, and chlorides of ammonium and sodium, 1.58. The second layer was found to contain only 79.2 per cent of iron, but no sulphuret or excess of carbon was discovered; while the third outermost layer was almost pure cast-iron.

Estimation of Acid in Fatty Oils.—M. Burstyn. —The oils are well mixed with twice their bulk of strong alcohol, 90 per cent at the least; this dissolves the acids which may be present in the oils, while hardly any of the latter are taken up. The alcoholic solution can be readily neutralised with a caustic soda solution of known strength. It is best to take 100 c.c. of the oil to be tested, to which an equal bulk of alcohol is added, care being taken to mix the fluids thoroughly. After some time the alcohol floats on the oil, and 20 c.c. of the former fluid should then be taken for titration. 100 c.c. of good machinery oil should not require more than from 0.4 to 1.4 c.c. of normal caustic soda solution for neutralisation.

Journal de Pharmacie et de Chimie, May, 1873.

Normal Microzymas Present in Milk considered as the Cause of the Spontaneous Coagulation; Alcoholic, Acetic, and Lactic Fermentation of that Fluid; and on the Normal Alcohol and Acetic Acid of Milk.—A. Béchamp. —The main cause of the spontaneous coagulation of milk is, according to the author, the presence therein of minute living organisms, which may be detected in the milk by first diluting it with from five to six times its bulk of creosote water (neither the degree of concentration, nor the mode of preparation of this fluid, are quoted), and next filtering the milk, care being taken to protect the filter from dust. The filter is first washed with ether, for the purpose of eliminating the butter; next, with a dilute solution of carbonate of soda, for the purpose of dissolving some caseine; and lastly with distilled water. On inspection with the microscope (magnifying power 500 diameters) the microzymas will be seen. In order to prove that the coagulation of milk is really due to these

organisms, the author states that he collected milk directly from the udders of a cow, filtered it through fine muslin previously washed with creosote-water, and caused the milk to flow into a vessel containing creosote-water and filled with carbonic acid gas, which was constantly passed through the milk. The vessel and milk quite saturated with that gas was next hermetically sealed, and placed in a drying-stove heated to from 35° to 40°; after two days, the milk was found to be coagulated. The author further ascribes to the microzymas the formation, in sour milk, not only of acetic and lactic acids, and also alcohol, which substances, however, also occur, but, of course, only in extremely small quantity. In fresh milk this is proved by the fact that the latter fluid yields, by distillation, after having been acidified with a slight excess of oxalic acid, alcohol and acetic acid. It should, however, be borne in mind that fresh milk always exhibits an alkaline reaction.

Jordery's Process for Preventing Accidents with Petroleum (Paraffin Oil).—M. Troost.—This paper treats on a proposition made by Jordery to convert petroleum into a butter-like mass by means of the addition of pulverised *Saponaria* root, previously mixed with some water. The result is, that a thick emulsion is formed which is far less inflammable than the oil itself. In order to restore the latter to its usual state, and render it fit for use to burn in lamps, it is only necessary to add to it a small quantity of pure carbolic acid (crystalline) or strong acetic acid. The author states, however, that also (owing to the expense of the *Saponaria* root, a product from the Levant) this process is not as yet practicable on the large scale.

Monatsberichte der Koniglich Preussischen Akademie der Wissenschaften zu Berlin, January, 1873.

Contains no papers relating to chemistry.

NOTES AND QUERIES.

Bursting of Cast-Iron.—A correspondent has forwarded the following extract from the *British Colonist*, a Halifax (Nova Scotia) paper, in the hope that some of our correspondents may be able to throw some light upon the curious phenomenon recorded in it:—"On Tuesday afternoon, while some workmen in Mr. John Hunter's foundry, Sackville Street, were engaged in breaking up a large block of cast-iron by the usual process, the mass burst with a loud report, one of the pieces striking one of the employees, a young man named Kennedy, causing serious internal injuries, from which he died yesterday morning. The deceased was one of the "Kennedy" boat crew of four who recently rowed against and defeated four oarsmen from H.M.S. *Royal Alfred*."

Cleaning Silver Articles.—The *Boston Journal of Chemistry* gives the following interesting account of the way in which the natives of East India clean silver articles. The East Indian jewellers never touch silverware with any abrasive substance. For all articles of the kind, even the most delicate, the method of cleaning they adopt is as follows:—Cut some juicy lemons in slices; with these rub any large silver or plated article briskly, and leave it hidden by the slices in a pan for a few hours. For delicate jewellery, the Indians cut a large lime nearly in half, and insert the ornament; they then close up the halves tightly, and put it away for a few hours. The articles are then to be removed, rinsed in two or three waters, and consigned to a saucepan of nearly boiling soap-suds, well stirred about, taken out, again brushed, rinsed, and finally dried on a metal plate over hot water, finishing the process by a little rub of wash-leather (if smooth work). For very old, neglected, or corroded silver, dip the article, with a slow stirring motion, in a rather weak solution of cyanide of potassium; but this process requires care and practice, as it is by dissolving off the dirty silver you obtain the effect. Green tamarind pods (oxalate of potash) are greater detergents of gold and silver articles than lemons, and are much more employed by the artisan for removal of oxides and fire-marks.

"Experiments with the Torsion-Rod for Determining the Mean Density of the Earth," forming vol. xiv. of the *Memoirs of the Royal Astronomical Society*. By Francis Bailey, Esq., Vice-President of the Society. London. 1843.

P. 38.—" . . . it is quite clear that both these experimentalists met with certain disturbing forces in the course of their inquiries for the cause of which they could not satisfactorily account, nor for the remedy of which did they make any successful attempt; but against which it has become very requisite that every precaution should be taken in the pursuit of any new experiments."

P. 39 (speaking of anomalies in his earlier experiments).—" . . . the arc of vibration during one and the same experiment would seldom decrease in the regular manner which it ought to pursue if the torsion-rod were guided by a uniform influence; and, moreover, that

in fact it would frequently increase contrary to all the known laws of bodies so circumstanced. I also remarked the same generally increasing tendency of the resting-point of the torsion-rod towards the masses when they were brought round to their *near* position."

"But totally different from either of these, and not to be explained on the same principle, was the frequent spontaneous motion of the torsion-rod when the masses were remaining in their *neutral* position where they could not exert any influence; I mean those occasional and more extraordinary movements in the arc of vibration which would frequently occur without any apparent cause. In these cases, the *time* of vibration would seldom differ from its mean period, and the *resting-point* would seldom vary from its usual position; but the arc would increase from little or nothing to a very considerable magnitude, and in some instances to such a degree that the balls would strike against the sides of the torsion-box. After continuing for some time in this oscillatory condition, the arc would gradually decrease, and the torsion-rod would ultimately recover its usual state of repose. These phenomena are the more remarkable, since in most of them during the whole period the weather has been generally very calm; and as to temperature, I have seldom been able to discover any material change in the thermometers distributed about the room."

"Notwithstanding these interruptions, I not only considered it proper to continue the experiments for some time in the usual manner, in the hope that I might thereby eventually throw some light on the probable cause of the anomalies, and perhaps be enabled to apply a correction for the effect of their influence; but also was induced to institute several new courses of experiments, as circumstances and suggestions occurred, for the express purpose of elucidating the subject. The theories of electricity, magnetism, temperature, and currents of air . . . were successively and frequently appealed to, and various experiments made to discover their probable effect on the results."

"Red-hot balls and powerful lamps were occasionally applied near the torsion-box with a view to raise an artificial temperature, and thus create a powerful influence; and, on the other hand, masses of ice have been employed for a similar purpose."

"I am principally indebted to Professor Forbes, of Edinburgh, for the most satisfactory removal of the principal anomalies that I had met with. This gentleman's intimate acquaintance with the theory of heat, and its various operations, effects, and influence, led him to agree with Cavendish in opinion that one source at least of the anomalies might arise from the *radiation of heat* from the masses when they were brought up to the sides of the torsion-box; and that this might even still operate, notwithstanding the interposition of the sides of the box and the intermediate boards already alluded to. As a remedy for this influence, he suggested the propriety of having the masses gilt, and also of procuring a gilt case as a cover to the torsion-box, for the purpose of preventing the effect of radiation, from whatever source it might arise. Acting upon this advice, I not only caused a gilt case to be made in the manner here proposed, but also caused the torsion-box itself to be previously covered all over with thick flannel. The masses and the plank on which they were placed were not gilt, as such an operation would be attended with some difficulty and inconvenience, but they were covered with gilt paper, and the whole of the interior of the framework was lined in a similar manner; but the 2 inch and 2½ inch leaden balls occasionally attached to the torsion-rod were gilt and burnished. And for the purpose of more effectually preventing the radiant influence of the masses, I altered the position of the stop so as to increase their distance from the torsion-box about 1½ inch more on each side. . . . The results soon convinced me that the proper mode had been taken for the removal of the principal source of discordance. For, although in some cases slight discrepancies may still appear to exist, as might be expected in any enquiry that involves so delicate a system of operations, yet when the discordances are of greater magnitude, they seem to be confined to one class of experiments, and to depend principally on the nature and construction of the material of which the suspension line or torsion-rod is composed, and do not materially affect the general result of the whole. In fact, I have met with very few experiments made in the regular mode of proceeding that are objectionable, or that need be rejected on account of any anomaly, properly so-called."

"I have already mentioned that the most striking evidence of a disturbing force was the irregularity in the magnitude of the arc of vibration; which has, however, now been removed by the alterations here alluded to. In order to satisfy myself that these alterations were the true cause of the removal, I have several times stripped the torsion-box of its coverings, and commenced experiments in that state; but I have always been obliged to abandon them, in consequence of the irregular influence of the masses on the arc of vibration on whichever side they were brought up."

MEETINGS FOR THE WEEK.

MONDAY, June 2nd.—Royal Institution, 2. General Monthly Meeting.

TUESDAY, 3rd.—Royal Institution, 3. Mr. J. H. Parker, "On Roman

— Archaeology."

— Anthropological, 8.

SUPPLEMENT TO THE CHEMICAL NEWS.

Vol. XXVII. No. 705.

ON ZINCO-BARIC CHLORIDE.

By G. J. WARNER, F.C.S.

It is well known that a concentrated solution of zinc chloride dissolves many other chlorides in large quantity. Double chloride of zinc with potassium, sodium, and ammonium chlorides have been already prepared. Barium chloride is extremely soluble in a solution of zinc chloride, sp. gr. 1.600; and if saturated the double chloride separates on cooling in small deliquescent needles. As the result of several analyses I find their composition to be— $2\text{BaCl}_2, \text{ZnCl}_2, 4\text{H}_2\text{O}$; in 100 parts—

	Calculated.	Found.
ZnCl_2	32.69	33.05
BaCl_2	50.00	50.03
H_2O	17.31	By diff. 16.93
	100.00	100.00

The amount of zinc is somewhat too high, owing to the difficulty of separating the crystals completely from the mother-liquor. The sp. gr. of the salt is 2.845.

I have also prepared zinco-magnesian chloride, but have not yet completed the analysis.

Ardwick Bridge Chemical Works, Manchester.

ON THE AMOUNT OF ALCOHOL CONTAINED IN BREAD.

By THOMAS BOLAS.

It appears to be generally believed that the alcohol which is formed during the process of panary-fermentation is either entirely or almost entirely expelled by the operation of baking, and it may be observed that in most cases writers on panification make no reference to the presence of alcohol in bread. For example, Dr. Miller ("Elements," 2nd ed., iii., p. 142) says—"During this baking, the alcohol formed by the decomposition of the sugar, which corresponds in quantity to that of the carbonic acid, is expelled." Experiment, however, has shown that, by distilling 2 ozs. of ordinary bread with water, and rectifying the distillate, it is easy to obtain a quantity of alcohol which is quite sufficient for recognition.

In order to determine the amount of alcohol quantitatively, about 1 lb. ($\frac{1}{2}$ kilo.) of each sample was distilled with water, an addition of about $\frac{1}{4}$ c.c. of oil being made to moderate the frothing, and the distillate was rectified a sufficient number of times, the alcohol being finally determined in the usual way. The results of the examination of six samples of new bread purchased at different shops in London are embodied in the following table:—

	Percentage of Alcohol.
I.	0.245
II.	0.221
III.	0.401
IV.	0.368
V.	0.249
VI.	0.399
Average ..	0.314

These samples were subjected to distillation as soon as practicable after baking, they having been obtained almost immediately after the opening of the shops; and, in order to ascertain the loss of alcohol which bread undergoes on keeping, portions of Nos. III. and VI. were exposed to the air in a moderately warm room for a week, after which time it was found that nearly two-thirds of the alcohol had evaporated, the amount remaining being 0.132 per cent and 0.120 per cent respectively. Although the presence of alcohol in the machine-made (aërated) bread would naturally create surprise, a portion of this kind of bread was, for the sake of comparison, submitted to distillation as in the above cases, and, as might have been expected, no alcohol was detected.

It is probable that the amount of alcohol contained in bread is too small to be of any dietetic importance, but it may be perhaps worth while to notice that forty 2-lb. loaves are about equal in alcoholic strength to an ordinary bottle of port.

I hope shortly to determine the amount of alcohol which dough loses on baking, not only when it is baked in large masses, but also when it is divided into small pieces (rolls) before baking.

CONSTITUTION OF HYDRACIDS IN SOLUTION, AND ON THE INVERSE REACTIONS WHICH THEY CAUSE.

By M. BERTHELOT.

THE author proposes to examine the true constitution of the liquids resulting from the union of hydracids with water, and what is its influence on their chemical reactions. The degrees of heat caused by dilution yield indications. Their progressive increase with the proportion of water corresponds to the existence of certain definite hydrates imperfectly formed in highly concentrated liquids, and whose production is completed by the addition of water. The changes observed in the law of curvature of a line representing the quantities of heat experimentally determined show the formation of a group of definite hydrates, the composition of which is nearly—

The existence of such definite hydrates is confirmed by proofs drawn from the study of the tension of anhydrous hydracids in their solutions. It is sufficient to examine if there exists some limit below which the hydracids cease to be carried away in a notable proportion by a gaseous current. The experimental limit at 12° C. was found to agree closely with the following proportions:—

These compositions agree with those found by Bineau, Roscoe, and Dittmar. Below these proportions, however, the hydracids are still carried off, though in smaller quantity. It is not till 8 to 9 H_2O_2 that the hydrochloric acid volatilised in a gaseous current ceases to act appreciably upon nitrate of silver. The foregoing limits are slightly affected by temperature and pressure. These trifling modifications agree well with the existence of certain definite hydrates—two in number at least—one of which is stable; while the other, less hydrated and less abundant, is in a state of dissociation, partial and varying with the temperature. It is the anhydrous hydracid and not some definite hydrate which is volatilised above the limit of stability. Concentrated solutions contain, therefore, the anhydrous acid; the proportion of which, at a given temperature, may be deduced from the composition of the invariable liquids. Such solutions are in reality a mixture of one or two hydrates in which the anhydrous acid is dissolved. The precipitation of dissolved alkaline chlorides by strong hydrochloric acid may equally serve to check the state of hydration of the latter

liquid. An experiment made with a cold saturated solution of chloride of potassium gave results corresponding closely to $\text{HCl} + 7.5 \text{ H}_2\text{O}_2$. In other words, strong acid takes away from a saline solution the water necessary to convert itself into a stable hydrate. The salt no longer finding the water necessary for solution, and being, moreover, insoluble in the hydrochloric hydrate, is precipitated in proportion to the water removed. The precipitation experiments concur with those of tension and of calorimetry to show the existence of a certain quantity of anhydrous acid in concentrated solutions, and they afford a new method for ascertaining the real state of hydration of bodies in solution. In fine, the dilute solutions of the hydracids contain only definite and stable hydrates; whilst concentrated solutions contain at the same time hydrates in a state of dissociation and a certain proportion of anhydrous acid. Hence arise contrary chemical phenomena produced by these two classes of solutions; the anhydrous hydracids effecting certain reactions, such as attacking sulphide of antimony, hydrogenising, organic compound, sulphur, and sulphurous acid, &c.; whilst the hydrated hydracids are inactive, or even produce inverse actions. The reversion of their reactions corresponds always to a reversal of their thermic sign; as the stable hydrates of the hydracids develop, at least in their reactions, the heat which has been disengaged at the moment of actual combination between the water and the anhydrous hydracid.

ON THE
EFFECTS OF MAGNETISATION IN CHANGING
THE DIMENSIONS OF IRON, STEEL, AND
BISMUTH BARS; AND IN INCREASING THE
INTERIOR CAPACITY OF HOLLOW IRON
CYLINDERS.*

By ALFRED M. MAYER, Ph.D.,
Professor of Physics in the Stevens Institute of Technology.

(Concluded from p. 253).

ALTHOUGH the cognate discovery by our countryman Page, in 1837, that iron bars produce sound on their magnetisation, has been carefully studied by Delezenne, De la Rive, Beatson, Marrian, and Wertheim, yet in the annals of science I have found only two experimental investigations, in addition to the one by Joule, on the phenomena of the elongation produced in iron rods on their magnetisation. The first is by Wertheim, in the *Ann. de Ch. et de Phys.*, 3e Serie, t. xxiii.; the second by Tyndall, contained in a paper entitled "On some Mechanical Effects of Magnetisation," published in his "Researches on Diamagnetism and Magne-Crystalline Action," London, 1870.

In Wertheim's memoir "On the Sounds produced in Magnetised Iron," all we find on the subject of the elongation of magnetised iron rods is the following:—"Here are the results of these experiments: the helix being placed so that its axis coincides with that of the bar, we do not observe any lateral movement, but only a very small elongation; this elongation rarely surpasses 0.002 m.m. [in rods about 970 m.m. long], and although visible is barely measurable; it is most pronounced when the helix [whose length was a little over $\frac{1}{4}$ th of that of the rod] encloses the extremity of the bar; it diminishes as the helix approaches the point [the centre] where the rod is clamped, and it is probable that when it is quite close to this point the elongation changes into a retraction, but I have never been able to observe the motion in this direction with any certainty. . . . I have already remarked that it was not possible for me to measure this

longitudinal traction; happily Mr. Joule has supplied that omission."

Dr. Tyndall opens his paper thus:—"Wishing, in 1855, to make the comparison of magnetic and diamagnetic phenomena as thorough as possible, I sought to determine whether the act of magnetisation produces any change of dimensions in the case of bismuth, as it is known to do in the case of iron. The action, if any, was sure to be infinitesimal, and I therefore cast about for a means of magnifying it. . . . I consulted Mr. Becker, and, thanks to his great intelligence and refined skill, I became the possessor of the apparatus now to be described. . . . The same apparatus has been employed in the examination of bismuth bars, and, though considerable power has been applied, I have hitherto failed to produce any sensible effect. It was at least conceivable that complimentary effects might be here exhibited, and a new antithesis thus established between magnetism and diamagnetism."

The apparatus used by Dr. Tyndall consisted of two vertical brass rods firmly cemented into a block of stone. Between these rods, securely fixed in the stone, were placed the rods of iron whose elongation he desired to measure. On the vertical rods slid a transverse bar of brass carrying "a vertical rod of brass, which moves freely and accurately in a long brass collar. The lower end of the brass rod rests upon the upper flat surface of the iron bar. To the top of the brass rod is attached a point of steel, and this point passes against a plate of agate, near a pivot which forms the fulcrum of a lever. The distant end of the lever is connected by a very fine wire with an axis on which is fixed a small circular mirror. If the steel point be pushed up against the agate plate the end of the lever is raised; the axis is thereby caused to turn, and the mirror rotates." The angular deflections of the mirror he determined by the method of Poggenдорff; that is, by viewing in a telescope the divisions of a fixed scale reflected from the mirror.

Dr. Tyndall gives the following account of his experience with this apparatus:—"Biot found it impossible to work at his experiments on sound during the day in Paris; he was obliged to wait for the stillness of night. I found it almost equally difficult to make accurate experiments, requiring the telescope and scale, with the instrument just described, in London. Take a single experiment in illustration. The mirror was fixed so as to cause the cross hair of the telescope to cut the number 727 on the scale; a cab passed while I was observing,—the mirror quivered, obliterating the distinctness of the figure, and the scale slid apparently through the field of view, and became stationary at 694. I went upstairs for a book; a cab passed, and on my return I found the cross hair at 686. A heavy waggon then passed, and shook the scale down to 420. Several carriages passed subsequently; the figure on the scale was afterward 350. In fact, so sensitive is the instrument, that long before the sound of a cab is heard its approach is heralded by the quivering of the figures on the scale.

"Various alterations which were suggested by the experiments were carried out by Mr. Becker, and the longer I worked with it the more mastery I obtained over it; but I did not work with it sufficiently long to perfect its arrangement. Some of the results, however, may be stated here.

Figure of Scale.

Bar unmagnetised	577
„ magnetised	470
„ unmagnetised	517

"Here the magnetisation of the bar produced an elongation expressed by 107 divisions of the scale, while the interruption of the circuit produced only a shrinking of 47 divisions. There was a tendency on the part of the bar, or of the mirror, to persist in the condition superinduced by the magnetism. The passing of a cab in that instance caused the scale to move from 517 to 534,—this

* Read before the National Academy of Sciences, in Cambridge, Mass.

is, it made the shrinking 64 instead of 47. Tapping the bar produced the same effect.

"The bar employed here was a wrought-iron square core, 1½ inch a side and 2 feet long.

"The following tables will sufficiently illustrate the performance of the instrument in its present condition. In each case are given the figures observed before closing, after closing, and after interrupting the circuit. Attached to each table, also, are the lengthening produced by magnetising and the shortening consequent on the interruption of the circuit.

Circuit.	Scale 10 cells.	
Open	647	
Closed	516	131 elongation.
Broken	581	65 return.
Open	637	
Closed	509	128 elongation.
Broken	579	70 return.
Open	632	
Closed	491	141 elongation.
Broken	568	77 return.

Circuit.	Scale 20 cells.	
Open	653	
Closed	475	188 elongation.
Broken	579	114 return.
Open	638	
Closed	452	186 elongation.
Broken	568	116 return.
Open	632	
Closed	472	160 elongation.
Broken	561	89 return.

"These constitute but a small fraction of the numbers of experiments actually made. There are very decided indications that the amount of elongation depends on the molecular condition of the bar.* For example, a bar taken from a mass used in the manufacture of a great gun at the Mersey Iron-works, suffered changes on magnetisation and demagnetisation considerably less than those recorded here. I hope to return to the subject."

That the tilt of the mirror in this instrument should be controlled alone by the molecular motions of the bar was hardly to be expected from a critical examination of the construction of the apparatus. The sudden upward push on the fulcrum might readily cause a minute permanent displacement of this delicate axis, and this change of position being greatly magnified by the lever and mirror would affect considerably the mirror's subsequent position of repose. Also, if on the above sudden and powerful impulse the long arm of the lever received a slight permanent flexure, or if the slender wire connecting the end of this lever-arm with the mirror-axis should become slightly elongated, these strains would determine a change of position in the mirror after contact with the battery was broken. The marked want of stability in the scale-readings I attribute to the fact that the weight of the indicating apparatus was placed on long brass rods, whose upper ends were unrestrained from partaking of tremors whose pulses were synchronous with the time of vibration of its system of weighted rods. These tremors transmitted through the ground to them caused the apparatus to partake of the nature of an instrument known to astronomers as "Hardy's Noddy," which is a species of inverted pendulum, and was even used by Captain Kater to detect any vibrations in the support of the pendulum used in his celebrated "Experiments for Determining the Length of the Pendulum Vibrating Seconds" (*Phil. Trans.* 1818, p. 42).

(To be continued.)

* This fact had previously been shown by Joule's experiments.

REPORT ON A MEMOIR OF M. BERTIN RELATIVE TO THE RESISTANCE OPPOSED

BY THE

HULLS OF SHIPS TO ROLLING MOVEMENTS.*

M. BERTIN gives in his memoir the results of experiments made on the decrease of rolling in calm water resulting from the passive resistance referred to, and the measurement of this resistance. He points out that the maximum amplitude of rolling is not sufficient to characterise ships with regard to the importance of their oscillations. Distinguish between the maximum amplitude, which M. Bertin proposes to call the *mobility*, and the mean and habitual amplitude which he calls the *agitation*, and which, relatively reduced, may be called by contrast the quietness (*tranquillity*). There are ships of great maximum rolling and of small maximum rolling, agitated and quiet, which must not be confounded with ships unstable and very stable: for very stable ships are in general very much agitated by rolling. To ascertain the laws of quietness in ships, it is necessary to measure both the waves and the rolling; and the instrument M. Bertin uses for this is one somewhat similar to that used by Mr. Froude. It consists of two pendulums, one of which takes 50 seconds and the other half a second in oscillation. Suppose a wave of 5 seconds, the period of the large pendulum will be ten times its duration, that of the smaller a tenth. If they are not too far from the axis of rotation of the rolling they will mark with reference to the ship's vertical longitudinal plane, the first one the absolute rolling, the second the relative rolling of the ship on the normal of the wave; provided always (for the second assertion) the dimensions of the wave are considerable with reference to the volume of hull carried by it. The difference of these two angles will be the inclination of the waves. Tracing-pencils fixed at the extremities of equal radii give two curves which can be easily examined and discussed. The Commission speak of M. Bertin's memoir as being one of considerable interest.

CORRESPONDENCE.

MILK OF BENGALI COWS.

To the Editor of the Chemical News.

SIR,—Some of your readers may be interested by the following results of some analyses which I have lately made of the milk of our little Bengali cows.

Total solids, as noted in the third column, were estimated by heating 5 grms. of the milk in a platinum dish for four hours in a steam-bath.

Casein was estimated by Mr. Wanklyn's now well-known method.

To estimate the sugar, 20 c.c. of the milk, mixed with 40 c.c. of alcohol, were put aside in a small flask for twenty-four hours. After filtering and washing, the fluid was evaporated to a syrupy consistence upon a water-bath. The residue was then made up with water to 100 c.c., the solution passed through a dry filter, and the sugar in it estimated by means of the copper solution.

Fat was estimated by two methods. One, the old method of evaporating to dryness 20 c.c. of the milk, mixed with sulphate of lime, and subsequent exhaustion with ether. The other method was as follows:—10 c.c. of the milk, with 10 c.c. of alcohol and 10 c.c. of ether, were introduced into a glass tube of about 50 c.c. capacity. The tube was then sealed, and exposed in a water-bath to a

* Abstracted from *Comptes Rendus*.

temperature of 180° F. for about two hours. When the tube had cooled, its end was broken off, the fluid contents drained into a small flask, and the solid matter remaining in the tube exhausted of fat by two or three boilings with ether. The contents of the flask were evaporated to about 10 c.c., then ether added to dissolve the fat, the ethereal solution separated, and evaporated to dryness in a very small weighed glass beaker. Before calculating the weight of the fat, the solubility in ether of the residue in the beaker was ascertained.

Anyone wishing to try this method of estimating the fat of milk, but who is unprovided with the means of sealing up the fluid in a glass tube, will find one of the long old-fashioned eau-de-Cologne bottles answer the purpose. The bottle must be provided with a very good cork, which must be tied down. The water-bath may be a tall cylindrical tin vessel. The bottle should be immersed to within an inch of its mouth in the water.

The following is the ordinary food of a Bengali cow, but the animal in the Bengali's hut plays very much the part of the Irishman's pig, and, with its master, has occasionally to manage as it best can:—About 12 lbs. of rice straw, 2½ lbs. of oil-cake, 1 lb. of husks of rice, sometimes a little very poor grazing, the water in which the family rice has been boiled, and about 3½ lbs. of water.

Age of Calf.	Weight of Milk given by the Cow each Day.	Solids of Milk.	Casein.	Sugar.	Fat.	Salts.
Months.	Lbs.	Per cent.				
1. 1	6½	15.12	5.50	3.98	4.98	0.76
2. 2	5	12.82	4.30	4.40	3.60	0.70
3. 2½	5	15.28	5.76	4.10	4.10	0.84

PATENTS.

ABRIDGMENTS OF PROVISIONAL AND COMPLETE SPECIFICATIONS.

Improvements in apparatus employed in the manufacture of salt. Otto Ernest Pohl, salt manufacturer and merchant, Liverpool, Lancaster. October 22, 1872.—No. 3116. The object of my invention is to produce salt in a merchantable condition at less cost. For that purpose I proceed as follows:—First. As means for economising fuel I arrange ordinary or convenient evaporating pans, one on the top of or over the other, and pass the flames, heating gases, or products of combustion over the brine at the lower pan, and at the same time under the bottom of the top pan. Doors are provided for withdrawing the salt from the bottom pan. Series of double pans may be used, and the flames, heating gases, or products of combustion and steam led over the brine. Second. As means for providing a cheap and durable cover for evaporating pans I construct such covers of a combination of wood or other suitable material and lead, lead being used to line the wood or other material forming the frame.

Improvements in furnaces for burning sulphurous ores. Alfred Vincent Newton, mechanical draughtsman, 66, Chancery Lane, Middlesex. (A communication from Konrad Walter, Augsburg, Bavaria). October 23, 1872.—No. 3142. The grate of the furnace on which the iron or copper pyrites (reduced to a suitable size) is laid is formed of bars which are capable of rocking in their bearings. These bars are made of such a section that when in their normal position the spaces between them will be sufficiently narrow to ensure the retention of the ore in

the grate, but when rocked will open spaces for the discharge of the ore that lies next the bars.

Improvements in protecting walls and other erections of brick, stone, iron, and wood from moisture. Robert Knott, chemist, Bolton, Lancaster. October 24, 1872.—No. 3154. This invention consists in the use of glue or similar substances and a salt, as bichromate of potash, to render it insoluble.

Improvements in obtaining caustic baryta. Thomas Cobley, Dunstable, Bedford, and John Edgar Poynter, Glasgow, Lanark. October 28, 1872.—No. 3194. In carrying out the invention barium sulphide is mixed with heavy oil or creosotic liquor and submitted to distillation. A combustible gas is obtained, and after being freed from sulphur compounds may be used as an illuminating gas, or as a fuel. The caustic baryta may be washed out of the residue, or it may be applied in many cases in its crude coke-like form.

Improvements in the manufacture of white-lead and apparatus therefor. William Thompson, 101, Wandsworth Road, Surrey. October 29, 1872.—No. 3202. This invention relates to improvements in the process of and apparatus used in manufacturing white-lead. The melting pan is made in compartments for regulating the temperature and securing the purity of the blue lead. This lead is made into thin sheets of open texture by pouring it into a revolving cylinder kept cool, and it is granulated by running it in a thin stream between a roller and an inclined knife, and receiving it in water. The sheets and granules are charged on trucks which are run upon rails into the chambers where the chemical reagents act on the lead so as to convert it into white-lead; the trucks charged with the converted lead being run out at opposite doors.

Improvements in bleaching textile fabrics and other fibrous materials. Baldwin Fulford Weatherdon, C.E., 77, Chancery Lane, Middlesex. (A communication from John Palliser, Robert McDowell, Adolphe Klopak, and Viçtor Grumel). October 31, 1872.—No. 3231. This invention consists in bleaching textile fabrics and other materials, without any previous preparation, by immersing them in a bath composed of chlorine, soda-salt, and sub-carbonate of soda neutralised by exposure to the oxygen of the air for a certain time.

Improvements in gas lamp blowpipe apparatus, part of such improvements being applicable to other spirit lamps. John Robert Harper, Clerkenwell, Middlesex. November 1, 1872.—No. 3233. The first part of these improvements consists in so constructing and regulating the aperture or apertures of the jet pipe or burner as to admit of benzoline, paraffine, naphtha, or other analogous oils or spirits being employed for generating gas under pressure in the oil or spirit vessels of gas lamp blowpipe apparatus. Another part of these improvements consists in applying two or more jet pipes to such apparatus, and also in attaching the jet pipes to the oil or spirit vessel of gas blowpipe apparatus by means of a gas union joint or otherwise. Another part of this invention relates to the application of an improved arrangement or construction of safety valve to the oil or spirit vessels of gas blowpipe apparatus. Another part of this invention relates to an improved construction of the wick tubes or holders of spirit lamps of all kinds, for the purpose of preventing the transmission of heat from the flame to the oil or spirit in the reservoir. Another part of these improvements consists in securing the spirit lamp in the case or frame below the oil or spirit vessel by means of a self-acting locking contrivance, which holds the lamp firmly in position. Another part of these improvements consists in so arranging the vessel in which the gas is generated, and the lamp through which the jet is directed, that the flame may impinge and act upon a horizontal surface either above or below the apparatus. Another part of these improvements in gas lamp blowpipe apparatus consists in arranging and mounting a series of such separate lamp apparatus in a case or frame for directing a number of gas jets upon an extensive surface required to be thus acted upon.

Improvements in metallic alloys applicable where copper, tin, zinc, brass, Muntz's metal, and other like metals and alloys are now used. Paul Auguste Desjardin, M.D., Paris. November 1, 1872.—No. 3244. The metals used in the formation of this improved alloy, or alloys, are copper, tin, zinc, arsenic, and nickel, in various proportions, according to the use and colour required. In some cases one or more of the ingredients are omitted.

Improvements in mixing, charging, and smelting iron ores. Edward Withy and William Gibson, West Hartlepool, Durham. November 2, 1872.—No. 3252. The object of this invention is to save fuel as much as possible. In effecting this, in the first place, the ores are crushed and ground, and the smaller they are ground the less fuel they take to smelt them. Second. The pulverised ores are mixed with the required quantity of lime and water to a stiff paste, which paste is forced into moulds or through dies, in a similar manner to drain tiles, the dies being made to give such shape or form to charging sections as will afford the greatest amount of heating surface, according to the weight and strength of the materials. With these sections are charged blast-furnaces, puddling-furnaces, cupolas, and vibratory-furnaces, in manner described in Letters Patent No. 2672, A.D. 1872, and more especially they are used in the improved puddling-furnaces described in said Letters Patent.

Improvements in fixing salt pans and in arranging the furnaces under the same. Joseph Parks, Wincham Boiler Works, Northwich, Cheshire. November 2, 1872.—No. 3260. According to this Provisional Specification the pan is supported on pillars, so that the whole or nearly the whole of the bottom becomes available as heating surface.

Improvements in the production of oxygen gas. James Alfred Wanklyn, 11, Harrington Street, Hampstead Road, Middlesex. November 2, 1872.—No. 3261. The feature of novelty of this invention consists in utilising the chemical properties of copper and oxide of copper in the preparation of oxygen gas.

THE CHEMICAL NEWS.

VOL. XXVII. No. 706.

ON ANILINE BLACK.

By CH. LAUTH.

IN May, 1869, I made public a process for dyeing aniline blacks by means of peroxide of manganese employed as mordant and oxidising agent. The practical application of this process, although it yielded results very satisfactory as regards the beauty and solidity of the blacks, was beset with difficulties, which caused it to be abandoned. But, as in this investigation I came upon several novel facts, it may be interesting for chemists desirous of carrying on further researches in the same field to know the exact conditions of my process and its attendant drawbacks.

Dyers are generally of opinion that, to dye yarns uniformly and regularly, drying must be avoided. The fixation and development of colours by means of dryings always gives rise to difficulties which are not encountered when we pass the yarn, without drying, from one bath to another. In dyeing thick bundles of cotton yarn, the interior of the hanks is much less exposed to the air than the exterior, and consequently, if the development of the colour is due to the action of the air, it is very probable that, in spite of the skill of the operator, inequalities of shade will occur. On the contrary, when the yarns are plunged successively into baths where they are uniformly moistened, and where they are in contact with the mordant and the colouring matter, there is much less probability of inequalities. In the case of aniline blacks, the inconveniences of a dry procedure have been already pointed out, and I do not see how they can ever be completely avoided.

On the other hand, aniline black, being necessarily absolutely insoluble, cannot be fixed like another colouring matter, but must be formed in the place which it is to occupy upon the fibre. To mix, with a salt of aniline, oxidising agents capable of producing the black, and to wash the yarn in such a bath until the colour is developed, is a method which does not yield good results, because the black, instead of fixing itself upon the fibre, remains suspended in the liquid. Mordanting the fibre with an oxidising agent which is soluble, or capable of being rendered so in the dye-bath, equally occasions the development of colour in the liquid, and consequently involves considerable losses.

It seemed to me that one method only for dyeing aniline blacks was practicable; fixing a salt of aniline upon the fibre in an insoluble state, and then passing it into an oxidising bath, or, inversely, fixing on the fibre an insoluble oxidising agent, and passing it subsequently into the solution of a salt of aniline. The second modification alone gives useful results; and, practically, it may be reduced to the fixation upon the fibre of oxidising agents rich in chlorine or oxygen, capable of easy decomposition, but incapable of diffusing themselves in the dye-bath and of wasting the colouring compounds with which the bath is charged. The agents in question are the higher oxides of manganese, binoxide and chlorite of lead, &c. Binoxide of manganese has especially attracted my attention.

Fixation of the Mordant.—The simplest process for fixing manganese upon cotton, wool, or silk consists in plunging these fibres into the solution of an alkaline manganate or permanganate. These salts are, unfortunately, very expensive. I had recourse, therefore, to the old process for manganese bronze, which consists in soaking the fibres in a salt of manganese (acetate, sulphate, or chloride), then passing them into caustic soda, and oxidising the protoxide of manganese thus fixed by means

of chloride of lime. To get an intense black, it is necessary to mordant in chloride of manganese at 40° B., working the cotton in this bath for an hour, wringing out well, then, without rinsing, pass it into boiling soda lye at 12° B., holding lime in suspension. Or the cotton may be first mordanted in a boiling manganese bath, and then passed through cold alkali. After the fixation of the oxide, the cotton is washed in much water, and passed into a lukewarm chloride of lime bath, regulating the proportion of this agent so that it may never be found in great excess, which might injure the fibre. It is best to add the chloride of lime little by little till the manganese bronze is sufficiently intense.

At first sight this method seems very practical, and, nevertheless, the difficulties met with have caused the process to be abandoned. The treatment with soda is offensive to the workmen, and roughens the cotton. The oxidation is a delicate process, as it is important not to injure the fibre. In short, if each step is simple, the whole requires precautions which yarn dyers are not accustomed to take. The process, it should be added, has given good results when applied in calico-printing.

I have endeavoured to modify the conditions of fixing the manganese. I mention a single remarkable result. A tissue, mordanted with manganese and placed in a chamber filled with ammoniacal gas, is found of a deep brown when taken out, the protoxide of manganese becoming readily peroxidised under these circumstances.

Dyeing.—The yarns, charged with manganese and well washed to eliminate all uncombined matter, are steeped in a cold acid solution of aniline. The colour is formed almost instantaneously. As soon as the bronze comes in contact with the aniline salt, the reaction takes place. The binoxide of manganese oxidises the aniline, and the black formed takes the place of the metallic compound. The operation is finished in one or two minutes, but the yarn may be left an hour in the bath without inconvenience. The proportions to be employed vary according to the intensity of the black desired. An excess of acid must be always used; thus, to 10 or 20 grms. of aniline per litre 60 grms. of sulphuric acid must be added, or to 50 grms. of aniline 150 of acid. If these limits are much exceeded the mordant may be attacked. The sulphuric acid may be replaced by other mineral acids, such as the hydrochloric, arsenic, &c. When taken out of the dye-bath, the cotton is well washed and passed into a boiling alkaline bath—soap or soda—to remove the last traces of acid and give the black its full beauty.

Brightening.—After dyeing, the shades may be modified and their intensity augmented by means of different agents. This indicates that, when the binoxide of manganese has completed its action, the colouring matter is still in a transition state, in which further oxidation may be useful.

Bichromate of potash, at 1 grm. per litre, salts of copper, mercury, and chrome, and especially a mixture of chlorate of potash, a salt of copper, and sal-ammoniac (1 grm. of each per litre), increases the intensity of the black. This treatment is applied after the washing subsequent to dyeing, and is carried on for half an hour at a boiling heat. It is followed by a second washing and by boiling in soap-lyes. The process described gives fine, solid blacks; it is speedy, and does not injure the fibre.

On the other hand, we must not forget the difficulties of the mordanting process, and the black stains off a little when rubbed.

In calico printing, my process is suitable for:—Black grounds. Black grounds, with discharge effects in all colours. Greys, produced by weaker mordants. Black patterns, along with greys and other shades capable of resisting the operations above mentioned (iron, chrome, copper, indigo, catechu, &c.). Joint application of black and indigo. Blue grounds, with white discharge and black patterns.

The nature of the coal-tar base employed is very important. Pure aniline, used alone, gives a very fine

intense black. Toluidine, a blue-grey. Methyl-aniline, a violet-black. Naphthylamine, a violet-brown.

The differences of shade are so striking that cotton cloth mordanted in this manner may be used to determine the comparative value of commercial anilines.

ON PROPYLAMINE AND TRIMETHYLAMINE, AND THEIR THERAPEUTICAL USE.

THE particulars in the following account are from a recent article by Prof. Gubler, of Paris:—

It is nearly twenty years since these two artificial alkaloids were introduced into the "Materia Medica" by an eminent St. Petersburg physician, and yet their existence seems to have been pretty much ignored by the majority of practitioners till quite recently.

The experiments of Awenarius, commenced in 1854 and published ten years later, attracted attention from only a few observers; among these an eminent Belgian, M. V. Guibert.

Some years later, the Russian doctor Kalenietzenko took up the work commenced by his fellow-countryman Awenarius, and published an interesting monograph on *propylamine medicines*. While Awenarius had applied propylamine in treatment of acute febrile disease, and specially rheumatism, Kalenietzenko regarded chiefly the alterative action which he considered it to have in chronic disease, especially the manifestations of scrofulous and tuberculous diathesis. He considered that cod-liver oil owed its efficacy to the volatile alkaloids contained in it, and other substances, also containing them among their principal constituents, would act in the same way. The idea is ingenious, but it is neither proved nor probable.

In June, 1872, an original memoir on the subject appeared in Italy, and, about the same time, one in America. Both publications excited the curiosity of medical men in France and England, and the therapeutical study of propylamine is now engaging considerable attention on both sides of the channel.

Propylamine is an excessively volatile liquid with a strong penetrating odour, like that of ammonia, and which, when diffused in the air, often resembles that from the brine of herring or of sardines. It is soluble in water, which it makes strongly alkaline, combines energetically with acids, and forms salts generally soluble in water and in alcohol, and capable of exhaling an odour of fish when either heated or treated with a fixed alkali. This alkaloid is found in the flower of hawthorn, in the fruit of sorb, in several *Chenopodia*, in spurred rye, in human blood and urine, and in cod-liver oil.

Propylamine and *trimethylamine* are isomers; their formula is C_6H_9N , but they differ somewhat in structure. The first may be represented by ammonia, NH_3 , in which 1 molecule of hydrogen is replaced by 1 molecule of propylene, C_3H_5 ; while, in the second, 3 molecules of methyl, C_2H_3 , are substituted for 3 molecules of hydrogen. These differences in grouping are necessarily connected with differences in physical, chemical, and physiological properties.

The two forms of C_6H_9N are commonly found together, and, owing to their extreme volatility and facility of metamorphosis, their extraction and isolation is very difficult. They have not yet been obtained, except in the state of mixture, and probably associated with other ammonia compounds. Moreover, they have only been obtainable in aqueous solution, more or less concentrated; whether by reason of the process of extraction, or the impossibility of preserving in the free state liquids so volatilisable—one of them (*propylamine*) boiling at $+45^\circ$, and the other at $+5^\circ$. They are therefore not administered in the pure state in medicine, and this may account for some of the discrepancy of statement as to their action.

Further, the very existence of propylamine in the complex substance used in medicine has been called in

question by some eminent authorities. Thus, Hofmann has sought in vain for it in the brine of herring; he has only succeeded in finding its isomer, trimethylamine. Silva, indeed, has obtained propylamine, but only in very minute quantity.

The uncertainty increases when one reflects that, according to the richness of the brine submitted to distillation, in presence of caustic potash, to expel the volatile alkalies, and according to the manner of the operation, we may obtain solutions more or less charged with active principles.

M. Petit's researches have brought to light some curious facts. He subjected to alkalimetric tests several different products sold under the name of propylamine, and with the following results:—

Using a sulphuric liquor, 1 c.c. of which exactly saturated 0.06 gr. of propylamine, he found 0.2 c.c. of the acid solution was necessary to neutralise 1 gr. of propylamine F; 0.3 c.c. for the same quantity of propylamine P; 0.6 c.c. for the product D; 1.2 c.c. for A; and 2.5 c.c. for that designated S.

Thus, the propylamine S, which contained 0.15 c.c. alkaloid per gramme, was more than ten times richer than the propylamine F, which contains only 0.012 c.c. There must be considerable disparity of action in medicines so unlike.

To all these causes of error should probably be added another, which may not be the last. Propylamine and trimethylamine, in presence of light or in contact with the atmosphere, is transformed gradually, and often quickly, into ammonia properly so-called, NH_3 , and into one or several other products representing C_6H_6 . In fact, propylamine solutions, immediately after being obtained, give a peculiar sweetish and slightly aromatic odour, approaching that of ammonia, but quite different; whereas, the emptied vessels, several days after, exhale the strong pungent odour of the volatile alkali, and appear, at least, to contain only pure ammonia.

Allowing for these sources of difference in observation, the following is what seems most clearly established as to the physiological action and therapeutical effects of propylamine and trimethylamine, or, rather, of propylamine solutions:—

Propylamine somewhat reddens the surface of the skin, causes a sensation of heat and burning in the first passages, and retards the pulse. Additional experiments are necessary to explain this retardation. The recent observations of Namiais do not solve the problem. He has observed, however, not only a diminution in the number of heartbeats, but a lowering of temperature and increase of the aqueous diuresis; so that he considers the action of propylamine similar to that of digitalis, but undoubtedly superior. He further observed that the pulse, retarded by propylamine, lost, at the same time, in force and fullness, indicating diminution of vascular tension, and, also, it would seem that the circulatory retardation is not produced by the same mechanism in the two cases.

Awenarius was the first to apply propylamine in therapeutics. Dr. Gaston, of Indiana, following his example, applied the alkaloid in treatment of acute articular rheumatism. Namiais, of Venice, guided, on the other hand, by his own researches, used it as a substitute for digitalis and its active principle, in cases where it was necessary to moderate the circulation and to increase the flow of urine, i.e., in organic affections of the heart, and dropsies dependent on them. More rarely, he has employed propylamine to stimulate perspiration.

There followed the researches of Dujardin Beaumetz, Besnier, and several other French physicians.

Dujardin Beaumetz does not regard propylamine as a mere sedative of inflammation or of fever, after the manner of quinine, but as an agent for extinguishing rheumatism locally, and repressing its fresh appearance.

"Unfortunately, a most attentive and prolonged study of the effects does not allow me to share the convictions of our distinguished colleague. My own experience,

somewhat limited as yet, but fortified by that of Pidoux, and other practitioners in the City hospitals, reduces the use of propylamine to that of a palliative for articular inflammation and rheumatic fever, which does not prevent relapses, and has not the extraordinary power which we might have desired."

For applying to the skin, Guibert recommends the use of pure propylamine. For mucous surfaces, it should be more or less diluted; for internal use, Awenarius prescribed it in potions of 1 to 4 grms. and more, in 125 grms. of distilled water aromatised with peppermint. This maximum has never been reached by the others. "For my own part, I have prescribed doses varying from 1 to 3 gr., and with the latter dose, I have only obtained obscure physiological results, and so slight and inconstant a retardation of the blood circulation that I could not affirm that it had the effects of medicinal action. In one case, on the contrary, I observed a general stimulating action, characterised by peripheric heat, pricklings in the skin, a tendency to perspiration, and restlessness in the limbs. But I am unwilling to draw any formal conclusion from this single fact; though it seems quite natural to expect stimulating effects from substances so closely allied to ammonia, and capable of progressive metamorphosis into a volatile alkali.

"My provisional conclusion is this—The concordant facts observed in Russia, Italy, the United States, and France, by eminent clinicians, warrant the belief that propylamine solutions exert a favourable influence on rheumatism and phenomena of circulatory excitation; still, the demonstration of this therapeutical action is not yet furnished, and truly scientific experimentation will only commence when we shall be in possession of one or of several agents well defined and always identical."

INVESTIGATIONS ON PARA-SULPHOBENZOIC ACID.

By IRA REMSEN.

(Continued from p. 215).

III. Formation of Parasulphobenzoic Acid from Sulphotoluenic Acid.

When substituting agents are allowed to act upon toluene, in the case of derivatives containing one substituting group, two products are formed. These are the para- and ortho- varieties. The former is always produced in much larger quantity than the latter. This has been proved by Engelhardt and Latschinoff,* and by Wolkow,† in the case of the sulphoto-derivatives. Wolkow proved that the products belonged to the para- and ortho-series, by converting them respectively into paraoxybenzoic and salicylic acids. According to the experiments of the chemists mentioned, the two sulphoto-acids can be separated by partial crystallisation of the potassium salts. In this way the para-salt was obtained in a perfectly pure condition, while the ortho-salt could not be freed entirely from the para-salt.

Now, as it had been shown that the oxidation of the mono-brom- and mono-chlor-derivatives of toluene yielded corresponding derivatives of benzoic acid, the idea naturally suggested itself that similar treatment of sulphotoluenic acid might yield the desired derivative of benzoic acid. My best hopes were satisfied. After a few experiments it became evident that by means of this reaction I could prepare parasulphobenzoic acid in unlimited quantity with but comparatively little labour.

The principal difficulty that presented itself was to be looked for in connection with the fact that the sulphoto-acid is exceedingly easily soluble; and some method had to be devised to extract it from the oxidising mixture, provided it were formed. A preliminary experiment, made with a small quantity of the potassium salts of the sulphotoluenic acids, showed that they were easily acted upon

by a mixture of sulphuric acid and potassium bichromate. Taking advantage of the suggestion of Fittig,* with the hope that the ortho-acid would be destroyed by the oxidising agents, I subjected the mixture of the two potassium salts to the influence of sulphuric acid and potassium bichromate in noted proportions. The oxidation, when once commenced by gently heating over a water-bath, proceeds rapidly to the end without the further aid of heat, and is completed in the course of a few minutes. The liquid becomes very hot, and foams somewhat; an evolution of gas takes place as long as the oxidation-process continues; and its cessation indicates the end of the operation. In order to extract the product from the mixture the whole was diluted with a large amount of water, and chalk added to the point of neutralisation. By this means the chromium oxide formed and the excess of sulphuric acid were precipitated, and in the solution remained the potassium salts of the sulphoto-acid or acids, together with some neutral potassium chromate. Baryta-water was now added in sufficient quantity to precipitate exactly the chromic acid present, this filtered off, and the filtrate evaporated almost to dryness. The colourless residue consisted of the potassium salts, together with some potassium hydroxide. The mass was first neutralised with sulphuric acid, and then a sufficient quantity of the latter added to set the sulphoto-acids free, care being taken to avoid any large excess. Moderately strong alcohol being now poured upon the mixture, an abundant deposit of potassium sulphate took place. This was filtered off, the salt well washed out with alcohol, and the alcoholic filtrate evaporated down again to a small volume. Potassium sulphate was again deposited. This was filtered off, washed out, &c., and the operation repeated a few times. Finally, the alcoholic solution was boiled for some time with water, and then evaporated to dryness over the water-bath. In this way the sulphoto-acids were obtained in a free state without impurities. The acid barium salts were prepared, and, on bringing their solution to the point of crystallisation, large acicular crystals were at once deposited, and these possessed the characteristics of the acid barium salt of parasulphobenzoic acid already described. They were analysed with the following results:—

0.5415 grm. salt was heated above 200°, and lost 0.0495 grm. H₂O; and gave 0.2130 grm. BaSO₄ = 0.12524 Ba.

	Calculated.		Found.
(C ₁₄ H ₁₀ S ₂ O ₁₀)	402	67.79	
Ba	137	23.10	23.13
3H ₂ O	54	9.11	9.14
	593	100.00	

This shows, then, conclusively that by the oxidation with sulphuric acid and potassium bichromate, the sulphoto-group of parasulphotoluenic acid remains intact. The conduct of the ortho-acid under like circumstances I shall refer to below. As far as I have been able to discover, by a consultation of the literature, this is the first attempt which has been made to oxidise sulphoto-acids in the manner described. The simplicity of the reaction and the satisfactory character of the results lead me to desire the further application of the principle involved, and I shall take the first opportunity to prepare a pure sulphotoxylenic and sulphoto-mesitylenic acid, with the object of subjecting them to the influence of oxidising agents, hoping thus to obtain an oxybibasic and an oxytribasic acid.

After having gained the necessary preliminary knowledge, I proceeded to determine the best conditions for the reaction. A large number of experiments were made, and as the result I would give the following directions:— Instead of first preparing the potassium salts of the sulphotoluenic acids, I employed a solution of the acids in sulphuric acid, considerable labour being thus saved. 25 grms. of pure toluene are dissolved in 200 grms. of

* *Zeitschrift für Chemie*, N. F., 5, 613.

† *Ibid.*, N. F., 6, 321.

* *Ibid.*, N. F., 7, 179.

fuming sulphuric acid without the aid of heat. When this solution has cooled down somewhat, two volumes of water are added, and the height of the liquid in the flask marked. Now more water is added, and the mass subjected to distillation until the liquid has reached the original volume indicated by the mark on the vessel. In this way any toluene which may have remained unacted upon by the sulphuric acid is removed. The solution is now allowed to cool to the ordinary temperature, and then 160 grms. of coarsely-powdered potassium bichromate gradually added. In order to start the oxidation the flask is placed on a water-bath, and gently heated for about ten minutes. During this time a commotion is noticed in the liquid, which gradually increases. An active foaming ensues, and when this has fairly begun the flask is removed from the water-bath. A uniform evolution of gas continues until the end of the operation, which occupies usually about twenty minutes in all. The gas evolved is carbonic acid, as was proved by appropriate reactions. In heating the mixture at first, it is absolutely necessary to place it on a water-bath; if the attempt be made to heat with a flame the flask invariably breaks. This is occasioned by the fact that the potassium bichromate lies at the bottom of the flask, and that the oxidation commences and goes on rapidly just at the spot where the heat from the flame is strongest. This spot immediately becomes very hot before the remainder of the glass has been at all heated, and from this spot a circular piece of glass inevitably drops, followed by the contents of the flask. When the operation is at an end, which, as stated, is indicated by the cessation of the evolution of gas, the whole is diluted with water, and then treated successively, as above described, with chalk, baryta-water, sulphuric acid, and alcohol. By this method, in the course of a few days, a very large quantity of pure acid barium parasulphobenzoate can be prepared.

Parasulphobenzoic Acid, $C_6H_4 \begin{Bmatrix} SO_2.OH \\ CO.OH \end{Bmatrix}$, is prepared from the barium salt by precipitating the barium exactly with pure sulphuric acid, and evaporating the solution. It is very easily soluble in water, and crystallises from a very concentrated solution in the form of beautiful, colourless, transparent needles. These, though very easily soluble, are not deliquescent. They fuse above 200° , but undergo decomposition before the fusing-point is reached. The meta-acid is deliquescent.

Potassium Parasulphobenzoate, prepared by neutralising and precipitating the acid barium salt by means of a solution of pure potassium carbonate, is exceedingly easily soluble in water, but crystallises finally in well-formed transparent needles.

Acid Sodium Parasulphobenzoate,—
 $C_6H_4 \begin{Bmatrix} SO_2.ONa \\ CO.OH \end{Bmatrix} + 2\frac{1}{2}H_2O$.

—This salt was prepared by neutralising and precipitating the acid barium salt with sodium carbonate, and then adding hydrochloric acid to the solution, evaporating, and allowing to crystallise. It forms beautiful, long, colourless, lustrous, stellate prisms. It is moderately easily soluble in cold water, more easily in hot water. The corresponding salt of the meta-acid is more difficultly soluble in cold water, and crystallises in laminæ. The two, when present in the same solution, cannot, however, be separated. The analysis of the salt gave the following results:—

0.3707 grm. of the salt, dried over sulphuric acid, on being heated gradually to 310° , lost 0.0607 grm. in weight; and then gave 0.102 grm. $Na_2SO_4 = 0.033038$ grm. Na.

	Calculated.		Found.
$(C_7H_5SO_3)$	201	74.72	
Na	23	8.55	8.91
$2\frac{1}{2}H_2O$	45	16.73	16.37
	269	100.00	

The remarkable fact will be noticed that the water of crystallisation is not driven off entirely until a high temperature (320°) is reached. All other salts of this acid, as well as of the meta-acid, which contain water of crystallisation, exhibit the same property, though not in such a marked degree as this one.

Barium Parasulphobenzoate, $C_7H_4SO_3.Ba + 2H_2O$.—This salt was obtained by neutralising a solution of the acid salt with barium carbonate. It is moderately easily soluble in cold water, very easily in hot water. It crystallises in small needles, which are grouped together in verrucose masses. The corresponding salt of the meta-acid is also easily soluble in water, but according to the descriptions given it contains no water of crystallisation. The analysis resulted as follows:—

0.4174 grm. salt, dried over sulphuric acid, on being heated gradually to 190° , lost 0.0411 grm. H_2O ; and then gave 0.2587 grm. $BaSO_4 = 0.15212$ grm. Ba.

	Calculated.		Found.
$C_7H_4SO_3$	200	53.62	
Ba	137	36.73	36.44
$2H_2O$	36	9.65	9.84
	373	100.00	

Acid Barium Parasulphobenzoate,—
 $(C_7H_3S_2O_3)_2Ba + 3H_2O$.

—The methods of preparation and analysis of this salt have already been given in detail. It is by far the most characteristic salt of parasulphobenzoic acid, and its properties are such as to render its preparation in an absolutely pure condition very simple. It is exceedingly difficultly soluble in cold water. When perfectly pure the length of the crystals is only dependent upon the depth of the liquid in which they are formed. It is more difficultly soluble, both in cold and in hot water, than the meta-salt. Like the meta-salt it does not give off its water of crystallisation entirely below 200° , and it may be subjected to a much higher temperature without the danger of decomposition.

Calcium Parasulphobenzoate is an amorphous powder which is somewhat more easily soluble in cold water than in hot, and is hence thrown down when a concentrated cold solution is boiled.

When the potassium salts, obtained in the preparation of acid barium parasulphobenzoate by evaporating the solution which has been treated with chalk and baryta-water, are fused with potassium hydroxide, a mixture of paraoxybenzoic and salicylic acids is obtained, the salicylic acid forming in some cases fully half of the product. This fact taken alone led at first to the conclusion that the methyl groups of both the para- and ortho-sulpho acids had been oxidised; and that thus not only parasulphobenzoic acid had been formed, but at the same time orthosulphobenzoic acid. Further investigation, however, showed conclusively that this was not the case, but proved another interesting fact, of which I shall speak below.

IV. Formation of Terephthalic Acid from Parasulphobenzoic Acid.

The recent experiments of V. Meyer* have tended to materially modify the prevalent views in regard to the constitution of the bi-derivatives of benzene. Meyer showed that ordinary sulphobenzoic acid, which, on the one hand, could be converted into oxybenzoic acid, could, on the other hand, be converted into isophthalic acid by fusing its potassium salt with sodium formate. As, according to the reigning ideas, isophthalic acid can only have the constitution indicated by the 1.3 position of its carboxyl groups, it became evident that oxybenzoic acid, which up to that time had been looked upon as belonging to the same series as phthalic acid, viz., the ortho (1.2) series, in reality belonged to the meta (1.3) series, of which

* *Berliner Berichte*, iii. Jahrgang, 112; and *Ann. d. Chem. u. Pharm.*, clvi., 265.

isophthalic acid is the most satisfactory representative. Salicylic acid thus became the 1·2 oxybenzoic acid, and the formulæ of a number of compounds were subsequently changed of necessity to place them in concordance with the results of the above reaction. But to take thus one experiment as the basis of a change as serious as that which ensued was looked upon by some chemists as insufficient; and indeed Meyer himself, in his first notice* on this subject, says—"Bei allen Schlüssen, die wir aus Reactionen, wie die oben beschriebene, ziehen, mahnt freilich die von Kekulé beobachtete Thatsache, dass die Phenolsulfasäure mit Leichtigkeit aus der Meta-Stellung in die Para-Stellung übergeht, zu grosser Vorsicht und ich werde daher auch die so eben aufgestellte Reihe nicht für völlig bewiesen halten, bevor ich nicht auch ein Glied der Meta-Reihe in gewöhnliche Phtalsäure werde übergeführt haben." Notwithstanding the fact that a great number of experiments were made with the object of more firmly establishing the principle adopted, by converting a member of the other series into the corresponding bibasic acid, they all failed; and the two analogous experiments of Meyer, viz., the conversion of sulphobenzoic acid into isophthalic acid, and the conversion of bromobenzoic acid into isophthalic acid, remained without support in their testimony. Attempts to apply the reaction to other fields were also unsuccessful, as shown in the experiments of Barth† and Ascher.‡ It is hardly strange, then, that with these circumstances the changes proposed by Meyer were not universally accepted; and those who opposed them on the ground that molecular re-arrangement might here play a role were certainly to some extent justified.

As I was now in possession of the para-acid§ corresponding to the meta-acid|| with which Meyer performed his experiment, it became an interesting question as to what the conduct of this compound would be when fused with sodium formate.

From the pure acid barium salt the potassium salt was prepared, and, the directions of Meyer being closely followed, this salt was fused with an equal weight of pure sodium formate. In order to bring the mass to the point of fusion a comparatively high temperature was required. It then remained in a semi-liquid condition, apparently evolving gas for a short time, finally becoming much darker in colour—in fact nearly black. At a certain point volatile products, evidently containing sulphur, were given off, the odour of which was intensely disagreeable. The operation was performed in a silver crucible, and the mass constantly stirred with a silver spatula. Occasionally the vapours which were given off took fire above the crucible, and, on the gas-flame being now removed from beneath, and the flame of the vapour being extinguished, the mixture continued red-hot for a short time, presenting the appearance of a burning coal. When all had cooled down to the ordinary temperature, the crucible and contents were placed in water, and this boiled. The solution thus obtained was filtered, and, when cold, was treated with sulphuric acid. Thus was thrown down a very voluminous, flocculent precipitate, of a decidedly dark colour. In order to purify the product, it was filtered off, and well washed out with hot water; then dissolved in ammonia, and this solution boiled with animal charcoal. A nearly colourless solution resulted, and on treating this with sulphuric acid the precipitate formed was almost white. An attempt was made to prepare the barium salt by boiling with pure barium carbonate. After long-continued boiling with a large amount of water the acid had disappeared, and the salt was in solution. On evaporating gradually the salt was deposited in crusts during the process. It proved to be of exceedingly difficult solubility in water, boiling as well as cold. A small portion of it appeared to have a tendency to crystallise. This was

separated from the powder and crusts, and repeatedly re-crystallised. It was also very difficultly soluble in water, and yielded an acid which resembled terephthalic acid in some properties. By means of various reactions, however, it was soon proved that this was not one of the phthalic acids, and it seemed probable that it might represent a variety of the thihydrobenzoic acids, the formation of which has been shown* to take place in the reaction of Meyer for the preparation of isophthalic acid. The amount of the substance obtained was not sufficient to permit of its close examination, its perfect separation from the other substance formed being impossible. The difficulty of separation threatened at the outset to be a serious obstacle in the way of deciding the point under consideration. One method after another was tried, but the results were decidedly unsatisfactory, until finally the mixture was subjected to the influence of an oxidising agent (sulphuric acid and potassium bichromate). By this means the thihydrobenzoic acid (?) was so changed in character as to become soluble, whereas the other constituent of the mixture was left behind in a pure condition unaffected upon. It was dissolved in ammonia, re-precipitated by means of a strong acid, filtered, and well washed out. In this condition it had the form of a very light, flocculent, white mass. It could be dissolved in boiling alcohol, and from this solution it was obtained in the form of microscopic needles which were deposited upon the sides of the vessel. This substance could not be brought to fusion. When heated in a capillary tube it sublimed from one part to the other before the flame, and was finally decomposed without fusing. It was almost absolutely insoluble in water, both boiling and cold; insoluble in ether. The pure substance could not be perfectly dissolved by boiling with barium carbonate. A small amount of the barium salt of the acid was, however, thus obtained, and this was very difficultly soluble in water, and did not crystallise. The calcium salt resembled this in every way.

These are the properties of terephthalic acid, with the exception of the conduct toward alcohol. To this I am not inclined to attach much weight, as the acid which is described as insoluble in alcohol is that which is obtained by oxidation of xylene, and the condition of this acid differs essentially from that of the light mass obtained by precipitating it from one of its salts. Further, I found that after being dried, the acid, as obtained by me, was also insoluble in alcohol. I would hence rather consider this conduct as indicating a property of terephthalic acid which had been overlooked. The substance was proved to have the composition of terephthalic acid by the following analysis:—

0·2325 grm. substance, dried over sulphuric acid, gave 0·4897 grm. CO₂=0·13355 grm. C and 0·0832 grm. H₂O=0·00924 grm. H.

	Calculated.		Found.
C ₈	96	57·83	57·44
H ₆	6	3·61	3·97
O ₄	64	38·56	—
	166	100·00	—

The proofs that terephthalic acid is formed when potassium parasulphobenzoate and sodium formate are fused together are thus conclusive. It remained, however, to show that neither phthalic nor isophthalic acid was formed at the same time. The crude product was boiled with water for a long time, and then filtered off. On allowing the filtrate to cool, a small quantity of substance was deposited in the form of powder. The whole was shaken with ether, which dissolved the powder and extracted whatever might be in solution. The original solution from which the crude acid had been precipitated was also treated with ether. On uniting the ethereal solutions and distilling off the ether, a residue was obtained which dis-

solved readily in alkaline carbonates. It was neutralised with barium carbonate. The barium salt was easily soluble and crystallised well. The free acid separated from this salt was easily soluble in hot water, and crystallised out on cooling. It had the fusing-point 120° , and all the other properties of *benzoic acid*. No other substance could be found. The quantity of benzoic acid obtained was very small in comparison to the whole quantity of the product, and its formation can easily be accounted for when we consider the character of the reaction.

Here then, at least, no molecular re-arrangement takes place; and this, taken in connection with Meyer's experiment, certainly makes the case strong enough to command attention. The reaction is thus shown to be capable of application for the purpose of determining the constitution of compounds, and the changes proposed by Meyer can be demanded with greater confidence than before. The proofs that paraoxybenzoic and terephthalic acids belong to the same series had already been given* by other reactions, though, acknowledging the described reaction, this would be the most direct proof of the fact.

(To be continued).

NOTICES OF BOOKS.

Practical Examples in Quantitative Analysis. By ERNEST FRANCIS, F.C.S., Demonstrator of Practical Chemistry, Charing Cross Hospital. London: H. K. Lewis, 136, Gower Street.

THIS small volume, as the author intimates in his preface, is intended for the use of medical students. It is undeniable that, if practising medical men are to fill the office of analysts under the "Public Health Act," they will certainly require a much more complete and practical knowledge of chemistry than they ordinarily possess at present.

The work treats of gravimetric, volumetric, and colorimetric analysis, the examples taken being the determination of total solids in water and in milk, of casein in milk of total solids, uric acid and albumen in urine, of chlorides in water, of hardness in water, urea in urine, of sugar and of cream. In colorimetric analysis we find examples of the estimation of ammonia, ureal and albumenoid, and of nitrates and nitrites in potable waters. In estimating the hardness of water, we observe that the author adheres to Clarke's original method, in preference to the modification introduced by Wilson. The directions for the determination of organic impurities in water are sound, being taken from Messrs. Wanklyn and Chapman, and there is no attempt to lead the student into the unwholesome mysteries of "previous sewage contamination." It would scarcely be possible to compress a greater amount of useful matter into the small compass of 57 pages.

A Review of "Prof. Reese's Review" of the Wharton Trial. By Prof. W. E. A. AIKIN, M.D., LL.D. New York: D. Appleton and Co.

A CRITIQUE on the evidence given, and on the theories put forward, to establish the innocence of the defendant in a poisoning case, with general remarks upon certain points of medical—or we might say chemical—jurisprudence. Those who remember the Tawell and the Palmer trials in England, or who have read Prof. Taylor's remarks on the lines of defence then adopted, will fully appreciate the attack which Prof. Reese—a witness, or rather scientific advocate, for the defendant Wharton—thought proper to make upon Dr. Aikin.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Under this heading will be found an encyclopedic list of chemical papers published abroad during the past week, with abstracts of all susceptible of advantageous abridgment. The two half-yearly volumes of the CHEMICAL NEWS, with their copious indices, will, therefore, be equivalent to an English edition of the "Jahresberichte."

NOTE. All degrees of temperature are Centigrade, unless otherwise expressed.

Berichte der Deutschen Chemischen Gesellschaft zu Berlin, April 28, 1873.

Methods for the Analysis of Water.—F. Tiemann. —The determination of hardness (magnesium) of sulphuric acid, nitrous and nitric acid, ammonia, sulphuretted hydrogen, and organic matter has led to constantly renewed discussion. Hence a re-examination of the methods recommended is desirable. *Determination of Hardness.*—The process for ascertaining the amount of alkaline earths in a water is always performed with a solution of soap, and depends on the double decomposition of the fatty alkaline salts in the soap, and of the lime and magnesia salts dissolved in the water. Insoluble lime and magnesia salts are separated out, and on shaking a froth is formed as soon as the decomposition is complete, and a slight excess of soap is present in the liquid. In the course of time three essentially different methods of determining the hardness by means of a soap solution have been made known; these are the old methods originally proposed by Clark, which has subsequently received several unessential modifications, the method of Boutron and Boudet, and that of Wilson. All three require that certain proportions of volume in respect of the quantity of water employed should be observed. It is in neither of these methods a matter of indifference whether—other conditions remaining unchanged—the hardness is determined in 10, 50, or 100 c.c. of water. All three render the determination of hardness possible only within certain limits, and in case of a very hard water require its dilution with distilled water to a normal volume. Clark, and the chemists who have slightly modified his process, use as standard test a dilute solution of soap, and a normal volume which some fix at 100 and others at 50 c.c. of water. As the consumption of soap-liquor in this method does not increase in the same ratio as the amount of calcic and magnesian salts present a table becomes necessary, showing the amount of soap solution corresponding to different degrees of hardness. Such tables, adapted to various conditions of concentration, have been drawn up by Clark, by Faisst and Knauss. The cause of the unequal decomposition of the soap-liquor may, perhaps, be found in the transient formation of soluble double compounds which at the outset of the process arise on the contact of soap and of the salts of the alkaline earths in very dilute solutions. In this manner the combination of an excess of the soap-liquor may be occasioned, and thus the latter may be deprived of the power of frothing when shaken. The alkaline salts (carbonates, sulphates, and chloride) formed in hard water on the decomposition of salts of alkaline earths by a larger amount of soap solution seem to diminish, and, finally, to hinder the formation of such double salts. The fact that highly concentrated neutral solutions of lime salts, mixed with soap, prevent it from frothing without giving an immediate precipitate (first pointed out by Maumene) agrees with this explanation. Boutron and Boudet avoid the above irregularities by applying a more concentrated solution of soap, and a normal volume of 40 c.c. of water. They use a peculiar measuring instrument (hydrotimeter) for reading off the concentrated test-liquid more easily. Its degrees do not correspond with the

cubic centimetres or its fractions. Wilson, who operates under conditions closely resembling those of Clark, obtains regularity of decomposition by adding 4 c.c. of a saturated solution of soda to the normal volume of 100 c.c. of water. In using Clark's process the author adopted the modification of Faisst and Knauss. 45 c.c. of soap solution correspond to 12 milligrams of lime in 100 c.c. of water. The soap solution for the method of Boutron and Boudet was so arranged that the amount filling 23° of the hydrometer exactly sufficed to produce the well-known permanent froth in 40 c.c. of water in which a neutral salt of lime, equivalent to 8·8 milligrams carbonate of lime has been dissolved. After deducting 1° of soap solution for the formation of froth 22° are employed in decomposing the 8·8 of lime salt in 40 c.c. water. 100 c.c. of the same water contain 22 milligrams of carbonate of lime. The transformation taken as regular shows 1° soap-liquid to 1 milligram carbonate of lime in 100 c.c. of water. If the degrees consumed are multiplied by 0·56 we find the corresponding milligram of lime in 100 c.c. of water. The soap-liquid for Wilson's process was so arranged that 36 c.c. corresponded to 12 milligrams lime in 100 c.c. of water which had been previously mixed with 4 c.c. solution of soda. In case of regular decomposition 3 c.c. solution of soap correspond to 1 milligram of lime in 100 c.c. of water. The hardness of a number of natural waters was determined according to these three methods. Some of the results are given below. In these and the following experiments the degrees of hardness are German, i.e., units of lime in 100,000; only in one case, which is specially pointed out, are French degrees employed, i.e., units of carbonate of lime in 100,000 parts of water:—

Total Hardness.			
Water.	Clark.	B. and B.	Wilson.
I. . . .	46·75	47·00	—
II. . . .	6·16	6·90	6·20
III. . . .	49·40	50·40	49·33
IV. . . .	31·56	32·70	31·60

Permanent Hardness.			
Water.	Clark.	B. and B.	Wilson.
I. . . .	21·52	21·90	—
II. . . .	1·90	1·20	—

The table of Faisst and Knauss was fully confirmed by the author's experiments. The procedure of Boutron and Boudet gives almost always higher numbers than the two other methods. In examining the method of Wilson we find that the addition of a saturated solution of carbonate of soda renders the decomposition of a soap solution by neutral salts perfectly regular. Wilson himself showed this in case of solutions of gypsum; and the author has experimented with a neutral solution of chloride of calcium, obtaining the following numbers:—

Water.	Carbonate of Soda.	Artificial Hardness.	Soap Liquid used.
100 c.c.	4 c.c.	12	36·0 c.c.
		9	27·0
		6	18·1
		3	9·2
		2	6·1
		1	3·3
		0·5	1·9
			0·6

With sulphate of magnesia the results are less favourable. Soap solution acts unequally quickly upon the compounds of the different alkaline earths and those of magnesia. Neutral salts of baryta are more readily decomposed than those of lime, and the latter more readily than magnesian salts. Equivalent quantities of calcium and magnesium compounds require for their decomposition exactly equal quantities of the same soap solution; but its action upon magnesian salts is not only much slower, but, if we do not work with very dilute solutions, incrustations and films are formed which prevent the portion of the magnesian

salts still in solution from acting upon the soap. This difficulty is rightly regarded as a flaw in all determinations of hardness by means of soap. It is not very prominent in the method of Clark, nor in that of Boutron and Boudet so long as the normal volume of water is duly diluted with distilled water, and as only small quantities of the soap-liquid are added at once. In Wilson's process it is rendered formidable by the addition of the soda solution. The foam disappears towards the end of the process so slowly that it is doubtful whether the addition of soap-liquid should be continued or not. The hardness of a water rich in magnesian salts is, therefore, easily found too low by Wilson's method, as the following figures show. Three solutions were prepared, the artificial hardness of I. being 20°; of II., 6·5°; of III., 12°. The hardness of No. I. was caused by magnesia alone; that of II., 4·5° by lime and 2° by magnesia; that of III., 9° by lime and 3° by magnesia:—

	Clark.	B. and B.	Wilson.
I. . . .	19·75	21·28	18·33
II. . . .	6·45	6·86	5·66
III. . . .	11·88	12·54	10·80

In case of Wilson's method the foam sometimes disappears after standing 15 to 20 minutes, and cannot be reproduced by shaking. Hence it appears that the original method of Clark is more accurate than either of the others, and is capable of the most general application. *Determination of Magnesia.*—The quantity of magnesian salt existing in solution in a water can be approximately estimated from the difference between the total hardness and the amount of lime as found by Mohr's process (titration with oxalic acid and permanganate), the number obtained being reduced to its equivalent in magnesia by multiplication by $\frac{1}{4}$ ths. The error occasioned by free carbonic acid—which also decomposes the soap solution—is neglected. In the author's experiments this amount was very trifling. The method of determining magnesia in a water by soap-liquid, after previous boiling and removal of the lime salts with oxalate of ammonia, cannot be pronounced trustworthy. It yields results which sometimes agree closely with those obtained gravimetrically, but on other occasions differs unaccountably.

Contribution to our Knowledge of the Ashes of Vesuvius.—C. Osterland and P. Wagner.—The sample analysed contained:—

Silica	47·53
Alumina	24·95
Iron (peroxide)	4·90
Iron (protoxide)	3·60
Magnesia	3·33
Lime	12·85
Potash and soda	1·41
Phosphoric acid	0·90

99·47

Traces of sulphur and sulphuric acid were also present.

Preparation of Iodphosphonium.—A. W. Hofmann.

Phosphines of the Propyl-Butyl and Amyl Series.—A. W. Hofmann.

Formation of Phosphines under Co-Operation of Reduction Processes.—A. W. Hofmann.

Further Observations on the Phosphinic Acids.—A. W. Hofmann.

These four papers are reserved for extended insertion.

On Propylen Diamin.—A. W. Hofmann.—The author prepares propylen diamin by acting with ammonia upon the bromide of propylen in sealed tubes, and afterwards, on the large scale, in an enamelled iron digester. Part of the liquid obtained was filtered from the deposit of bromide of ammonium, and digested with oxide of silver. A strongly alkaline liquid was obtained, in which, after the ammonia and alcohol had been expelled, chloride of platinum gave a pale yellow precipitate, perfectly in-

soluble in water. The rest of the liquid was treated with excess of solid potash, and heated in a retort to expel ammonia and alcohol. Propylen diamine was obtained as an oily liquid. After it had come over, less volatile bases made their appearance, secondary and tertiary diamines and triamines. Pure propylen diamine is a colourless, transparent, not very mobile liquid, boiling at 120°C . It consists of—

Carbon	48.64
Hydrogen	13.52
Nitrogen	37.84

100.00

And its formula is $\text{C}_3\text{H}_{10}\text{N}_2$. Its affinity for water and for carbonic acid is remarkable.

Certain Carbonic Acid Derivatives of Isobutyl.—E. Mylius.—The compounds described are sulphoethyl-dioxy-carbonate of butyl, sulphobutyl-dioxy-carbonate of ethyl, trisulphocarbonate of butyl, and butyl-trisulphocarbonate of soda.

Action of Chlorine upon Isobutyl Aldehyde.—G. A. Barbaglia.—The author attempted to prepare a monochlorated compound, analogous to Schröder's monochloro-valeraldehyde, but obtained a substance having the composition $\text{C}_3\text{H}_5\text{ClO}$, and approaching more nearly to monochloroacetone and epichlorhydrine.

Oils of Mustard.—Eugene Dell.—A preliminary notice.

Kresotenic Acid.—R. Biedermann and W. Pike.—The material employed by the authors was cresol, in which sodium was dissolved under simultaneous introduction of a stream of carbonic acid gas. The pure acid obtained fuses at 174°C ; crystallises from hot water in fine shining needles, closely resembling salicylic acid. It takes a deep violet colour on contact with chloride of iron.

Certain Derivatives of Cresol.—R. Biedermann.—The author attempted to obtain substitution products with chlorine, and formed a monochloro-cresol, $\text{C}_7\text{H}_7\text{ClO}$, fusing at 56° and volatilising undecomposed at 240°C . This substance gives few reactions. It was not found possible to obtain from it orcin or any isomeric body by fusion with potassa or by boiling with alcoholic potassa. Cresol-sulphuric acid was prepared, and its potash-salt fused with potassa gave indications of proto-catechucic acid. The production of orcin was next attempted by means of iodides of cresol. Proper quantities of iodic acid and iodine were dissolved in dilute alkali, and the theoretical amount of cresol was added. A yellowish-red body was ultimately obtained, which, with ammonia, took a red colour like orcin, and dissolved in fixed alkalies with a deep red colour. It did not yield the deep violet colour with perchloride of iron, and the results on analysis did not agree with orcin.

New Members of the Stilben Group.—Julius Strakosch.—This paper gives an account of the preparation and properties of dinitro-stilben, amido-nitro-stilben, and diamido-stilben.

Contribution to the History of the Thio-amides.—R. Wanstrat.—The author has studied the action of iodine upon thio-cuminamide, amidothio-benzamide, and the action of nascent hydrogen upon the product resulting from the treatment of thio-cuminamide with iodine.

Contributions to the History of the Derivatives of Salicylic Acid.—R. Wanstrat.—An account of the preparation and properties of salicylic acid-anilide, salicylic acid-nitrilide, and salicylic acid-toluidide.

Derivatives of Salicyl-Aldehyde.—W. Haarmann.—Salicyl-aldehyde agrees with the remaining aldehydes in its behaviour with substituted ammonia. Salicyl-anilide, $\text{C}_{13}\text{H}_{11}\text{NO}$, has been previously obtained by Schischkoff, with separation of water on heating together equal volumes of aniline and salicyl-aldehyde. The author obtained monobrom-salicylanilide by acting with aniline

upon monobrom-salicylaldehyde under the same conditions. It crystallises from alcohol in brick-red needles, and consists of $\text{C}_{13}\text{H}_{10}\text{BrNO}$. Anhydrous hydrocyanic acid reacted violently with a mixture of salicyl-aldehyde and aniline. The result was hydrocyanate of salicyl-anilide, in pure white crystals insoluble in water, but readily soluble in alcohol and ether. On exposure to the air, it becomes light red without decomposition; but if exposed to a continuous heat of 100°C . it is resolved into hydrocyanic acid and a resinoid residue. Its composition is $\text{C}_{14}\text{H}_{12}\text{N}_2\text{O}$. Salicyl-paranitrilide is formed by the action of paranitriline on salicyl-aldehyde. It forms pale yellow crystalline needles, which melt at 115°C . An attempt to combine this body with hydrocyanic acid yielded a bright red substance fusing at 205°C ., insoluble in water, and sparingly soluble in boiling alcohol and ether. The action of ammonia and hydrocyanic acid upon salicyl-aldehyde was also examined, the result being a red crystalline body of the composition $\text{C}_{29}\text{H}_{21}\text{N}_3\text{O}_3$.

Transformation of Naphthylamine into Nitronaphthal.—G. Andreoni and R. Biedermann.—A preliminary notice. Naphthylamine is first converted into aceto-naphthylamine. From this mononitro-acetonaphthylamine is obtained, which, by the action of alkalies, becomes mononitro-naphthal.

The Sulphacids of the Methylanilines.—G. A. Smith.—The author has examined the behaviour of methyl-aniline and dimethylaniline with sulphuric acid. The monosulphacid of dimethylaniline is a crystalline substance of the composition $\text{C}_8\text{H}_{13}\text{NSO}_4$.

New Series of Diamines which Occur as By-Products in the Manufacture of Methylaniline.—A. W. Hofmann and C. A. Martius.

The Violet Colour-Derivatives of the Methylanilines.—A. W. Hofmann.—These two long and important papers are reserved for full insertion.

Constitution of the Benzol Substances.—Theodore Petersen.—A theoretical, not to say hypothetical, paper, consisting to a great extent of "graphic formulæ."

Aromatic Compounds Containing Silicium.—A. Ladenburg.—The author has formed and examined silicium-phenyl trichloride, ortho-silico-benzoic ether, and silico-benzoic acid, both anhydrous and hydrated.

Derivatives of Cœrulignon.—C. Liebermann.—The author has previously described cœrulignon as a by-product obtained in the purification of wood vinegar, and belonging to the chinon class. He has now investigated the constitution of the substance, and has formed some of its derivatives and reactions.

Constitution of the Allyl Compounds.—A. Kekulé and A. Rinne.—Allyl alcohol is readily attacked by dilute chromic acid. Even in the cold the odour of acrolein is observed, and carbonic acid escapes. If the liquid is distilled, after some time formic acid is detected in the distillate, but not acetic acid. If the same alcohol is treated with nitric acid, there is no odour of acrolein. Formic acid without acetic appears in the distillate, and there is much oxalic acid in the residue. The behaviour of the iodide and cyanide of allyl with chromic and nitric acids was also examined.

On a Compound of the Cyanide of Allyl and Ethylic Alcohol.—A. Rinne.—The new compound consists of $\text{C}_4\text{H}_5\text{N}, \text{C}_2\text{H}_5\text{O}$. Its boiling-point is between 173° and 174° .

A New Formation of Stilben.—Br. Radziszewski.—Phenyl-acetate of baryta with a slight excess of sulphur was submitted to dry distillation. The distillate contained a hydrocarbon, which, when purified and examined, proved to be stilben. The yield is abundant.

On Graphite.—J. Stingl.—(See p. 264.)

On Ortho-Nitrophenol Sulphacids, Amidophenol Sulphacids, and a new Nitrophenol.—Jul. Post.—A preliminary notice. The author reviews the results of

previous experimentators and announces the discovery of four amido-sulph-phenols.

On Chinon Substances.—Th. Petersen.—A theoretical paper, which would not be intelligible without the accompanying diagrams.

Hydrates of Monobasic Acids.—A. Geuther.—A controversial essay directed against Messrs. Grimaux and Henninger. The author considers that it is not his fault if his results, published three years ago, have not become known to these gentlemen.

Remarks on H. Fudakowsky's Paper "On Slow Oxidation as an Agent for rendering Oxygen Active."—Ed. Schaer.—The author confirms the facts cited by Fudakowski. He states that not alone insulation promotes the slow oxidation of the hydrocarbons and the simultaneous ozonisation of oxygen, but that heat, within certain limits, has the same influence. During a series of experiments performed in the year 1866, with the view of confirming Schœnbein's results on the antozone present in resins, he (Schaer) proved that on carefully distilling, in a place sheltered from direct light, a mixture of water with oil of turpentine, of juniper, of lemon, and other terebenes in a relatively large volume of air, both the distillate and the watery layer of the residual matter give unmistakable indications of the presence of peroxide of hydrogen; whilst the oil, which has passed over, behaves as if it had been exposed for some time to the action of oxygen under the influence of light. Schœnbein considers this behaviour of the essential oils with oxygen as a main support of his doctrine of the polarisation of oxygen. It may perhaps be assumed—without prejudicing the existence of antozone, so often asserted and so often denied—that the differentiation of oxygen occurs in all cases of slow combustion, that is, whenever air and water act upon organic or inorganic materials.

Derivatives of Bromtoluol as Evidence concerning the Nature of the Bromtoluols.—H. Huebner and P. Hässelbarth.—A table of the formulæ and properties of the parabromtoluol sulphuric, and parabromnitrotoluol sulphuric β and α compounds.

Oxidation Products of Colophonium.—Jos. Schreder.—A preliminary notice. The author is examining the oxidation products of the so-called turpentine-resins, which, unlike the aromatic and the umbelliferous resins, are not attacked and decomposed by melting alkalies, but are oxidised by nitric acid forming acids not yet studied. Colophonium yields isophthalic and trimellitic acids.

Monobasic Saccharate of Lime.—R. Benedikt.—The author has succeeded in preparing a salt, to which he assigns the formula $C_{12}H_{20}CaO_{11}$, and which contains—

Calcium	10.80
Carbon	37.44
Hydrogen	5.57
Oxygen	46.19

100.00

Diphenyl-benzol.—G. Schultz.—When benzol is passed through incandescent tubes, we obtain along with diphenyl several bodies boiling at higher temperatures. Berthelot has isolated three of these, and distinguished them as—chrysen, benzerythren, and bitumen. The author considers that Berthelot's chrysen is diphenylbenzol, its analysis showing $C_{18}H_{14}$, whilst the formula of chrysen is $C_{18}H_{12}$.

Synthesis of Aromatic Acids.—W. Weith.—The author recently made known that on treating phenylated oil of mustard with powdered copper, cyanphenyl is formed by the removal of sulphur, and passes into its isomer benzonitril. He has subsequently discovered that the above reaction is generally applicable, and that the isomeric telyl mustard-oils are easily transformed into

the corresponding nitriles. In this manner, pseudo-toluidine is converted into orthotoluic acid, and solid toluidine into paratoluic acid.

Brüning's New Method of Preparing Magenta.—Coupier.—The author claims priority in the preparation of magenta, by treating aniline with nitro-benzol.

A Question of Priority concerning some Thermo-Chemical Laws.—J. Thomsen.—The author considers that Berthelot and others are claiming and receiving the credit of having made certain generalisations which he himself announced several years previously.

Affinity of Oxygen for Chlorine, Bromine, and Iodine.—J. Thomsen.—An examination of the amount of heat liberated during the formation of chloric, bromic, iodic, hypochlorous, and periodic acids.

New Universal Support.—R. Muencke.—The construction and uses of this piece of apparatus could not be understood without the accompanying illustration.

New Conversion of Oil of Turpentine into Cymol.—A. Kekulé.—Iodine was added to the oil of turpentine-oil in small successive portions, the reaction being each time assisted towards the end of heat before a fresh quantity was added. In this manner 10 grms. of cymol were obtained from 50 grms. oil of turpentine and 22 grms. of iodine.

Bulletin de la Société Chimique de Paris, tome xix., No. 10, May 20, 1873.

Binitro Compounds of the Higher Homologues of Benzol.—A. Rommier.—In his previous investigations, the author obtained from the oils of coal two xylenes, one of which was soluble in sulphuric acid of ordinary concentration, and the other insoluble. The soluble xylene yielded, with fuming nitric acid, two binitro compounds, the mixture of which melted at $61^{\circ}C$. These two bodies, re-crystallised from alcohol, have been investigated by Des Cloizeaux, who found that the less soluble binitro-xylene, α , formed crystals belonging to the clino-rhombic system, whilst the more soluble binitro-xylene, β , formed rhombic crystals of the triclinic system. On further examination it was, however, found that the salt β , on repeated crystallisation, was transformed into α . The author concludes, therefore, that there is merely a single binitro compound corresponding to the xylene soluble in sulphuric acid. To sum up: by the action of ordinary sulphuric acid upon the oils of coal, we separate two xylenes, two cumenes, and two cymenes:—I. Hydrocarbides insoluble in sulphuric acid, accompanied by a certain quantity of formenic hydrides. (1). Xylene, boiling between 139° and 140° ; its binitro compound melts at 92° , and forms clino-rhombic crystals. It differs from the binitro methyl-toluen of Fittig, which forms two kinds of crystals, the less soluble in long colourless needles, melting at 123.5° , the other in brilliant, transparent, monoclinic crystals, fusible at 93° . (2). Mesitylene, boiling at 165° to 167° , is the most abundant member of the series; its presence in coal oils was shown by Fittig, and its binitro compound examined by Des Cloizeaux. (3). Cymene, according to theory, should boil at 196° , the gradation of boiling-points between benzol and its homologues being 28° to 29° . Its direct verification did not succeed, from the presence of formenic hydrides boiling at adjacent temperatures. II. Hydrocarbides soluble in sulphuric acid and regenerated by distillation. (1). Iso-xylene, boiling at 139° to 140° . Its binitro compound melts at 92° to 93° ; very fragile prisms. (2). Pseudocumene, boiling at 165° to 167° , and forming two binitrocumenes fusible at 86° . (3). The cymene of this series is contaminated with naphthalene.

On Aniline Black.—Ch. Lauth.—(See p. 275).

Reply to the last Communication by M. Berthelot on the Mercurial Calorimeter.—P. A. Favre.—A continuation of the controversy between these two savants (see vol. xviii., p. 388).

On Silk Dyeing, and on the Combination of Silk with Sulphuric Acid.—M. E. Durrwell.—The author takes, for the foundation of his views, the hypothesis that silk forms, with acids, true compounds, capable of uniting with the coal-tar colours and with other dyes. Having ungummed silk to set the fibroine at liberty, he boiled it for a day in distilled water, to remove the last traces of the soap employed in this operation. It was then extracted with alcohol, so as to leave pure fibroine, which invariably gave an alkaline reaction. This silk was then dyed in a bath of litmus and very dilute sulphuric acid. The litmus serves here at once as reagent and as colouring matter. The colour is thus entirely fixed in the silk; but, on neutralising the bath with a trace of magnesia or of caustic soda, the blue litmus went back into solution, except a trace which was still absorbed by the silk. This experiment may be indefinitely repeated on the same colour-bath by rendering it alternately acid or neutral. It is the same with the coal-tar colours, but, as these have a great tinctorial power, the experiment is less striking and decisive than with litmus. On treating 2 parts of fibroine with 1 part of sulphuric acid in the cold, combination at once takes place. Heat is developed, which must be kept down as much as possible by cooling the capsule, otherwise the silk will be completely resolved into glucose and ulmic compounds. After an hour's time, the reaction is complete. The brown liquid is filtered over asbestos, diluted with three or four times its bulk of water; the excess of acid is neutralised with baryta, filtered, and evaporated. A mass is thus obtained which, on treatment with alcohol, leaves a true compound of fibroine and of sulphuric acid. It is a white, transparent, horn-like body, soluble in water. The solution, if treated with an alkali, gives a precipitate of fibroine.

Bulletin de l'Academie Royale des Sciences des Lettres et des Beaux-Arts de Belgique, No. 4, 1873.

Note on a Fossil Bird discovered in the Rupel Clay.—P. J. van Beneden.

New Process for Preventing Ships' Compasses being affected by the Iron and Steel which is employed in the construction, as well as occasionally carried as cargo by the vessels.—M. Glossner.

Revue Scientifique de la France et de l'Etranger, No. 47, May 24, 1873.

This number contains no original chemical matter.

Revue Hebdomadaire de Chimie Scientifique et Industrielle, par Ch. Mène, No. 19, March 13, 1873.

Delaunay's Apparatus for the Alcoholometric Assay of Wines.—The specific gravity of the wine is taken in its ordinary state. Another equal portion of wine is boiled in a flask till all the alcohol is expelled and the thermometer immersed; it rises to 100° C. The boiled liquid is then put into the hydrometer glass, made up to its original bulk with distilled water, and its specific gravity again determined. From the difference of these two specific gravities (before and after the expulsion of the alcohol) the amount of alcohol is found by means of tables accompanying the apparatus. It is necessary that the temperature of the wine should be 15° C. If it be higher or lower corrections are required.

No. 20, March 20, 1873.

This number contains nothing touching in the remotest manner upon chemistry.

No. 21, March 27, 1873.

Galzy's Insecticide.—A laudatory notice of an insecticide of unknown origin.

New Mode of Preserving Organic Substances from Decay.—M. Lanjorrois.—The author proposes to

add to the substances to be preserved 1 per cent of magenta! The process has been applied to slices of beef, which, after being kept for several months, yielded—after being washed and boiled—very good soup. (Should this method of preserving food become general, we trust that the magenta employed will be free from arsenic).

MISCELLANEOUS.

Memorial to Justus Liebig.—Many of our readers will be glad to know that at a meeting of the German Chemical Society, held in Berlin, on April 28th last, it was resolved to erect a statue in honour of the late illustrious chemist, Baron Liebig, and to invite his pupils, friends, and chemists of all nations, to contribute towards the funds necessary for that object. Drs. Warren de la Rue, Frankland, Gilbert, Odling, Stenhouse, and Williamson, are members of the Committee, and communications and subscriptions may be sent to Dr. Hugo Müller, 110, Bunhill Row, E.C.

PATENTS.

ABRIDGMENTS OF PROVISIONAL AND COMPLETE SPECIFICATIONS.

Improvements in the means of and apparatus for removing obstructions from gas-pipes. George Goldsmith and James Dilkes, Leicester. November 4, 1872.—No. 3269. The object of this invention is to afford means for clearing gas-pipes, especially services, and consists in forming a plug furnished with a barrel which is to be filled with gunpowder and inserted in the offending pipe. The charge is then to be fired by striking a percussion-cap placed on a nipple on the outside of the plug, when an explosion ensues and the removal of any obstruction is the result.

The manufacture from mahogany and other woods of a colouring matter similar to cashoo. Charles Rave, merchant, Cureghem-lez-Bruxelles, Belgium. November 4, 1872.—No. 3270. This invention consists in extracting from mahogany and rose woods a matter having all the properties of the brown cashoo of commerce. The matter is obtained by first reducing the wood to powder, then roasting or torrefying the powder, afterwards washing and boiling it, and finally concentrating it by evaporation into a syrupy or a dry state.

Improvements in cements. John Raitton Williams, merchant, Manchester, Lancaster. November 4, 1872.—No. 3272. This invention consists in mixing powdered zinc with cement.

Improvements in obtaining anthracene and in apparatus connected therewith. John Berger Spence, merchant, Manchester, Lancaster. (A communication from Jos. C. F. Cheever, New York, United States of America). November 4, 1872.—No. 3273. This invention consists of a pitch tank, tempering reservoir, still, and condenser, for the purpose of obtaining anthracene from coal-tar pitch by a continuous process.

Improvements in treating and utilising certain refuse animal and vegetable substances, and the application of the resulting substances or matters to various manufactures. William Glazier, 235, Drake Street, Rochdale, Lancaster. November 5, 1872.—No. 3278. This invention consists in utilising scrap leather and the fibrous refuse from wool, cotton, flax, and jute manufactures and spent dye-woods by combining these materials with silicates, animal carbon, gas-tar, asphalt, and bitumen in the several ways described in the Specification so as to make an improved plastic composition and also various kinds of waterproof and fireproof goods and vessels. The leather is first treated with a hot solution of alkali, and then subjected to the action of steam or boiled in water under pressure until it is reduced to a gelatinous mass, to which is added glycerine and pyroligneous acid. To this mixture is added a solution of pyroligneous acid and tannic acid or of pyroligneous acid and alum. The whole is then thinned with boiled oil and mixed with mineral oxide, or dry silicate colours. This mixture is called the "cementing mixture." By adding to this mixture the fibres hereinbefore referred to, a plastic composition or pulp is made, which may be rolled, moulded, or otherwise formed into various useful and ornamental articles. In making "shaped" felted articles the fibres are first disintegrated or devilled, then deposited on moulds and the shapes saturated with the cementing mixture. In making composite sheets or slabs the devilled fibres are felted into sheets, which sheets are saturated with the cementing composition, then coated with the plastic composition. The whole is then pressed, after which, should the slab not be sufficiently thick, other saturated sheets are placed on the first until the slab is made of the required thickness. In making waterproof slabs or sheets the felted sheets are saturated, as before described, pressed, and dried; then coated with a waterproofing composition of ground carbon and gas-tar mixed with naphtha or turpentine or benzine, and are covered with melted asphalt or bitumen, on which a second prepared sheet is placed and the whole

pressed together. The waterproofing composition above described is applicable to the protection of iron from rust and also to the coating of vessels and articles made according to this invention. In making floor-cloths the "cementing composition" is mixed with silicate pigments, cotton fibres, spent dyewoods, and ground cork and spread on the felt. In making tessellated floor-cloth or imitation parquetry the sheets of felt are saturated with the cementing composition and coloured according to the pattern required. The pieces constituting such pattern are then cut out and affixed to a sheet of felt or canvass by means of the cementing composition. In making circular and other shaped receptacles, tubs, "akips," boxes, tanks, and cisterns, a shape is made by cementing brown paper on a suitable mould. The shape is then coated with the cementing composition and when dry coated with the plastic composition hereinbefore described, after which it is again dried and pressed and finished by coating with the waterproof composition. Where great strength is required, strips of calico are affixed around the vessel. The waterproofing and cementing compositions hereinbefore described are applicable to the preservation of iron ships.

Improvements in artificial fuel, part of which improvements having reference to the means or apparatus employed in the manufacture of the same. Edward Joseph William Parnacott, engineer, Leeds. November 6, 1872.—No. 3292. The employment of powdered, dissolved, or liquefied waste caoutchouc or gutta-percha for fuel either separately or in combination with other substances such as clay, road mac, fine riddings or small coal or dust of coke, also shale, peat, and sawdust; these are thoroughly mixed or agglomerated in a pug-mill, and afterwards moulded into any required form in a brick-machine of ordinary construction, and afterwards dried.

NOTES AND QUERIES.

Formic Acid.—Will any of your readers inform me whether commercial formic acid, formate of lead, or any other formiate is used for dyeing or any other process in the arts?—S. S.

"Experiments with the Torsion-Rod for Determining the Mean Density of the Earth," forming vol. xiv. of the *Memoirs of the Royal Astronomical Society*. By Francis Baily, Esq., Vice-President of the Society. London. 1843.

P. 43.—"The torsion-rod is never at absolute rest, but is constantly in a state of vibration on its centre; and consequently when the end of it is viewed at a distance with the telescope, it appears to oscillate on each side of a mean point, called the *resting point*."

"This resting point, however, is by no means permanent or stationary, and seldom remains in the same position for any length of time, even when the torsion-rod is not influenced by the approach of the masses. The extent and direction of its disturbance, as well as its rate of motion when so disturbed, are very variable, and seem to depend on causes which have not been sufficiently accounted for, but which may in some measure arise either from slight changes of temperature, or some latent alteration in the component parts of the suspension line."

P. 44.—"It must be confessed, however, that discordances sometimes arise which cannot wholly be attributed to change of temperature, but to some other occult influence with which we are at present unacquainted."

P. 64.—"Seeing that the results came out nearly the same, with the same balls, in whatever way the experiments were varied, I next tried the same plan with the glass balls, the single results of which . . . had been somewhat more discordant, and the mean result somewhat greater, than the results obtained by the other balls. I was agreeably surprised at finding the single and daily results in such good accordance with each other, . . . although I was still at a loss to account for the slight difference which still existed between the results with these balls and the heavier ones."

"I next tried what the result would be with balls made of a substance still lighter than that of glass. I therefore . . . affixed the 2 inch ivory balls. . . the mean result agrees very well with the general result of the experiments previously made with the 2 inch lead balls; although it is somewhat less than that deduced from the experiments made with the glass balls, which was contrary to my expectations."

P. 65.—"Conceiving that there might be some unexplained cause even for this slight discordance, I resolved to repeat the experiments under the same circumstances. . . The mean result was still less than in the former series. I am unable to account for the cause of this discordance in any other way than by the known fact that in all cases, where the deviation is so small, . . . a slight variation in the position of the resting point makes a considerable difference in the resulting density. . . But, in the present instance, the single and daily results are in very good accordance with each other. . . Some other varying force, therefore, would seem to be in operation."

"Wishing however to ascertain whether a similar diminished result would be produced by a repetition of the experiments with the glass balls, I again submitted them to another trial. . . the mean result showed that the same diminished difference had here also been produced as with the ivory balls; and for the cause of which I cannot account in any other way than that to which I have just alluded."

P. 67.—"I am still however unable to assign any satisfactory reason why the mean result of these heavy balls should be so much less than that of the lighter balls. There is nothing on the face of the experiments that indicates any cause for a suspicion of error, and therefore we must look for some other explanation."

MEETINGS FOR THE WEEK.

MONDAY, 9th.—Geographical, 8.30.
TUESDAY, 10th.—Photographic, 8.
WEDNESDAY, 11th.—Society of Arts, 8.
Geological, 8.
THURSDAY, 12th.—Royal, 8.30.
Royal Society Club, 6.
FRIDAY, 13th.—Astronomical, 8.
SATURDAY, 14th.—Quekett Microscopical Club, 8.

TO CORRESPONDENTS.

* Vol. XXVI. of the *CHEMICAL NEWS*, containing a copious index, is now ready, price 11s. 4d., by post, 12s., handsomely bound in cloth, gold lettered. The cases for binding may be obtained at our office, price 1s. 6d. Subscribers may have their copies bound for 2s. 6d. if sent to our office, or, if accompanied by a cloth case, for 1s. Subscribers wishing to complete their sets of volumes are requested to apply to the publisher, who will give them information respecting scarce numbers and volumes. Vol. xxvii. commenced on Jan. 3rd, and will be complete in twenty-six numbers. *READING CASES*, price 1s. 6d. each, post free, may also be obtained at the Office.

D. McPherson.—See No. 683.

W. B. M.—Received with thanks.

THE CHEMICAL NEWS.

VOL. XXVII. No. 707.

ON THE ACTION OF HYDROCHLORIC ACID

ON CODEINE.

By C. RUSSELL WRIGHT, D.Sc.,
Lecturer on Chemistry in St. Mary's Hospital Medical School.

In a former paper, written in conjunction with E. L. Mayer (*Chem. Soc. Journ.*, [2] xi., 211), it has been shown that when morphine is treated with hydrochloric acid at 100° the first action that takes place is, apparently, the addition of the elements of hydrochloric acid; the subtraction of the elements of water taking place subsequently, bases being formed of the composition—

A base homologous with the last one has been obtained already from codeine, viz., the so-called "chlorocodide" obtained by the late A. Matthiessen and the author (*Proc. Roy. Soc.*, xviii., 83). In order to trace out more completely the history of the formation of this base and its subsequent decompositions, codeine was heated on the water-bath for two and a half hours with from 6 to 8 parts of strong hydrochloric acid; a less time of digestion being found to give too little product for successful isolation. The resulting acid liquid was nearly neutralised by caustic soda, and precipitated by sodium carbonate, which threw down a white amorphous precipitate; this was separated by filtration, dissolved in hydrochloric acid, again precipitated by sodium carbonate to remove traces of codeine, and finally dissolved in ether. The ethereal solution yielded a viscid non-crystalline hydrochloride on agitation with a few drops of hydrochloric acid. In physical properties this exactly resembled "chlorocodide" hydrochloride: but on analysis it yielded numbers indicating the presence of a less chlorinated base as well—

0.3005 grm. gave 0.673 CO₂, and 0.166 H₂O

0.3165 " " 0.229 AgCl.

These numbers agree with the composition—

which represents a mixture of the hydrochlorides of two bases homologous with (P) and (R) derived from morphine as above mentioned—

	Calculated for	Found.
	$\{ 4C_{36}H_{42}N_2O_6, 2HCl \}$	
	$\{ 5C_{36}H_{42}N_2O_6, 2HCl \}$	
Carbon	61.04	61.08
Hydrogen	6.12	6.14
Chlorine	17.83	17.90

Hence, writing $\bar{C}$ for $C_{36}H_{42}N_2O_6$, the formation of these bases may be expressed thus:—

Homologue of (P)
from Morphine.

Chlorocodide.

It thus appears that the formation of "chlorocodide" is preceded by that of a base containing only 1 proportion of chlorine to 36 of carbon, and, hence, "chlorocodide" must be represented by a C₃₆ formula at least; but as ordinary codeine is obtained from "chlorocodide" by the action of water (Matthiessen and Wright, *Proc. Roy. Soc.*, xviii., 83), it appears that "chlorocodide" is a derivative

of ordinary codeine and not of any of its higher polymericides, and hence that ordinary codeine must have a C₃₆ formula too.

When the action of hydrochloric acid at 100°, or slightly higher, (the liquid being kept *very* gently boiling) is carried on for a longer time methyl chloride is evolved; but after a time this ceases, and after 10 hours or so all the codeine has become converted into a mixture of two isomeric bases of composition intermediate between that of morphine and that of "apomorphine." One of these bases is soluble in ether, and yields crystalline salts much resembling those of apomorphine; the other is insoluble in ether, and belongs apparently to the tetra series.

The product of 10 hours' action of hydrochloric acid was precipitated by sodium carbonate, well drained on filters, and digested with ether. The ethereal solution agitated with hydrochloric acid gave a crystalline hydrochloride, which gave the following numbers after re-crystallisation:—

0.3065 grm. gave 0.7380 CO₂ (H₂O lost).

0.2255 " " 0.5350 CO₂ and 0.132 H₂O.

0.1015 " " 0.0480 AgCl.

	Calculated.	Found.
C ₆₈	81.6	65.28
H ₇₆	7.6	6.08
Cl ₄	14.2	11.36
N ₄	5.6	4.48
O ₁₀	16.0	12.80

The portion insoluble in ether was dissolved in hydrochloric acid, and fractionally precipitated by sodium carbonate to remove colouring matters. Finally a non-crystalline hydrochloride was obtained which gave the following numbers after drying at 100°:—

0.2980 grm. gave 0.716 CO₂, and 0.170 H₂O.

0.2980 " " 0.1365 AgCl.

	Calculated.	Found.
C ₁₃₆	163.2	65.28
H ₁₅₂	15.2	6.08
Cl ₈	38.4	11.36
N ₈	11.2	4.48
O ₂₀	32.0	12.80

From its physical properties it appears probable that this base forming the crystalline hydrochloride belongs to the series of derivatives from the *double* polymericides (dicodine, "apomorphine," &c.); hence it is viewed as having a C₆₈ formula, and as possessed of the composition of the "diapo" derivative of (hypothetical) dimorphine, i.e., as $\bar{M}_2 - 2H_2O$. Hence it may be conveniently termed *diapo-dimorphine*.

Similarly, the isomeric base insoluble in ether produced simultaneously evidently belongs to the tetra series, and hence may be conveniently termed *tetrapo-tetramorphine*, having the composition $\bar{M}_4 - 4H_2O$, and a C₁₃₆ formula.

Both compounds give a blood-red colouration with nitric acid, a lighter evanescent red with sulphuric acid and potassium dichromate, and a dirty purple with ferric chloride. They may be viewed as produced by the mutual reaction, polymerisation, and demethylation of the two bases first formed by the action of hydrochloric acid on codeine, viz., the homologues of (P) and (R) similarly obtained from morphine.

Homologue of P.

"Chlorocodide."

Diapo-dimorphine.

where $\bar{C} = \bar{M} + 2\text{CH}_2 = \bar{M} + 2\text{CH}_3 - \text{H}_2$, i.e., where codeine is dimethylated morphine.

It has been formerly shown* by the late A. Matthiessen and the writer that when either "chlorocodide" or codeine is heated to 140° to 150° under pressure with excess of strong hydrochloric acid methyl chloride is formed, and apomorphine apparently identical with that from morphine is produced. It thus appears that the action of hydrochloric acid on codeine at 100° is different from that at 140° to 150°, the elements of two proportions of water (per C₆₈) being removed in the first case, and

those of four proportions in the second, diapodimorphine, and tetrapodimorphine being respectively formed. These two bodies are alike in physical properties and qualitative reactions, but they differ much in physiological properties. Dr. Gee found that the latter produced the same emetic action as apomorphine from morphine; whilst the experiments of Dr. J. G. Blackley prove that the former base is destitute of emetic action on cats, only producing profuse salivation when subcutaneously injected in doses up to 0.1 grm.

It hence appears that the removal of the elements of water from (hypothetical) dimorphine, and from tetramorphine respectively, gives rise to an alteration in the physiological properties of the derivatives, the emetic action on cats being the more marked in the first case the more H₂O is removed, the less so in the second case. Thus the following table exhibits the change in physiological action:—

Name of Base.	Relation to Morphine.	Physiological Action.	Observer.
		<i>Di Series.</i>	
Dimorphine.	$\bar{M}_2$.	(?)	—
Diapodimorphine.	$\bar{M}_2 - 2\text{H}_2\text{O}$.	{ Produces profuse salivation, but no vomiting (cats). }	Dr. J. G. Blackley.
Tetrapodimorphine.	$\bar{M}_2 - 4\text{H}_2\text{O}$.	{ Moderately powerful emetic (cats). Very powerful emetic (man). }	Drs. Gee and Stocker.
		<i>Tetra Series.</i>	
Tetramorphine.	$\bar{M}_4$.	Very powerful emetic (cats).	Dr. Stocker.
Diapotetramorphine.	$\bar{M}_4 - 2\text{H}_2\text{O}$.	Do. do. (cats and dogs).	Do.
Tetrapotetramorphine.	$\bar{M}_4 - 4\text{H}_2\text{O}$.	{ Produces profuse salivation, but no vomiting (cats). }	Dr. J. G. Blackley.
O&apotetramorphine.	$\bar{M}_4 - 8\text{H}_2\text{O}$.	{ Neither salivation nor vomiting produced (cats). }	Do.

Action of Hydrobromic Acid on Codeine.

The results just detailed render it probable that the formation of "bromocodide" is preceded by that of a less brominated base probably $(\bar{C} + \text{HBr}), 2\text{HBr}$, which appears, in fact, to be the case.

On heating codeine to 100° for three hours with 5 to 6 parts of 48 per cent hydrobromic acid, precipitating with sodium carbonate, solution of precipitate in ether, and agitation of ethereal solution with hydrobromic acid, a viscid non-crystalline hydrobromide is obtained, much resembling bromocodide hydrobromide, but containing less bromine.

After drying at 100°, the gum-like mass gave these numbers—

0.3410 grm. gave 0.6310 CO₂ and 0.158 H₂O.
0.3000 " " 0.2205 AgBr.

These numbers agree with the composition—

	Bromocodide.	
	Calculated.	Found.
Carbon ..	50.47	50.47
Hydrogen ..	5.14	5.15
Bromine ..	31.15	31.27

Whence it appears that the first action of hydrobromic acid on codeine is perfectly parallel with that of hydrochloric acid; it has already been shown, however (*Proc. Roy. Soc.*, xix., 371, 504), that the further action of hydrobromic acid gives rise to products not identical with those formed by means of hydrochloric acid whether acting at 100° or at higher temperatures.

From its physical properties, it appears probable that the "deoxycodine" thus formed belongs to the dicodine series, i.e., its formula contains C₇₂; whilst the "bromotetracodine" simultaneously produced is a tetra base, i.e., its formula contains C₁₄₄; the formation of these two bases may, then, be explained by the following equation:—

This reaction is different from that formerly given (*loc. cit.*), where the action was supposed to consist, at any rate partly, in the replacement of bromine by hydroxyl; it now appears more probable that this replacement does not take place, the hydroxyl group being subtracted from a portion of the formula different from that to which the bromine symbol is added.

The table on next page represents the relation to codeine and morphine of the derivatives obtained up to this time from codeine; * inasmuch as the "apomorphine" obtained from codeine by the action of hydrochloric acid at 140° to 150° appears to be identical with that derived from morphine under the same or other conditions, whilst the bases obtained by the action of hydriodic acid and phosphorus from codeine and morphine appear to be identical also, the conclusion may be drawn that codeine is actually dimethylated morphine, i.e., $\bar{C} = \bar{M} + 2\text{CH}_3 - \text{H}_2$.

All these derivatives may be regarded as formed by the addition of the elements of *m* proportions of hydriodic, hydrochloric, or hydrobromic acid to, and the subtraction of *n* proportions of water from, a polymeride either of codeine or of morphine, or a base derived from one or other of these by the addition or subtraction of hydrogen; in short, all of these derivatives (together with those obtained from morphine as starting-point, and tabulated in a previous paper [*Journ. Chem. Soc.*, II., xi., 211]) may be included in one or other of the two formulæ:—

* Matthiessen and Wright, *Proc. Roy. Soc.*, xvii., 460; xviii., 83. Wright, *ibid.*, xix., 371, 504; xx., 8, 278.

* *Proc. Roy. Soc.*, xvii., 460; xviii., 83.

DERIVATIVES CONTAINING αC_{36} (CODEINE SERIES).

Where p varies from 0 to 8,

$x = 1, 2, 3$, or 4 (giving rise to the mono, di, tri, and tetra series respectively ;

m varies from 0 to 4 ;

X is either Br, I, or Cl ;

n varies from 0 to 12.

In many instances the bases thus produced from codeine and morphine (some forty in number) have not been named, the complexity of their composition, and the scanty knowledge as yet possessed of their relations to other substances precluding the possibility of a systematic nomenclature ; where names have been given from motives of convenience in reference, the chief point aimed at was to indicate the nature of the relation of the derivative to the parent base ; thus, the name "diapotetramorphine" indicates that the formula of the base is obtained from that of the "tetra" polymeride of morphine by the subtraction of the elements of two proportions of water, *i.e.*, that the composition is indicated by the expression—

Objections may be raised to the use of the prefix "apo," to indicate the removal of the elements of water, on the ground that there is no reference to water in the etymology of the term ; but the prefix "anhydro" is open to the more serious objection that it really indicates the contrary of the prefix "hydro," which refers to the addition, *not of the elements of water, but of hydrogen* (hydroquinone, hydrocyanic acid, hydrocinnamic acid, &c., &c.) ; whilst the prefix "meta," which has been used in the sense in which "apo" has been employed during these researches (Barker, *Am. Journ. Sci.*, vol. xlv., Nov., 1867), is also used to indicate a particular class of benzene derivatives, which are in no way producible from the parent body by the removal of the elements of water. The inconvenience and ambiguity occasioned by the inconsistent meanings thus attachable to the terms "anhydro" and "meta" are such as to warrant the invention of a new term when precision in language is desired.

Each one of the bases mentioned in the following table form a hydrochloride (hydrobromide or hydriodide) containing as many proportions of hydrochloric (hydrobromic or hydriodic) acid as there are nitrogen symbols in the formula.

Three other compounds, not included in the foregoing tables, have also been obtained, viz. :—

Chloro-dicodeine-dimorphine-hydrochloride—

which is homologous with, and intermediate between, chloro-tetracodeine and chloro-tetramorphine hydrochlorides. Also the compounds $C_{136}H_{214}I_6N_8O_{44}.8HI$ and $C_{136}H_{206}I_6N_8O_{32}.8HI$, obtained by the action of hydriodic acid on the compounds $(\bar{M} + H_4)_4 - 4H_2O$ and $(\bar{M} + H_8)_4 + 4HI$, respectively.

These two latter derivatives may be represented by the formulæ—

and—

differing from all the other derivatives of $(\bar{M} + H_4)_4$ and $(\bar{M} + H_8)_4$ in that the elements of water are added on, instead of being subtracted, while the elements of six proportions of hydriodic acid are also added on, four being the highest number in the other cases.

Royal Society.—At a meeting held last night the following gentlemen were elected Fellows of the Royal Society:—William Aitken, M.D.; Sir Alexander Armstrong, M.D.; Robert Stawell Ball, LL.D.; John Beddoe, B.A., M.D.; Frederic Joseph Bramwell, C.E.; Staff-Captain Edward Kilwick Calver, R.N.; Robert Lewis John Ellery; Lieut.-Colonel James Augustus Grant, C.B., C.S.I.; Clements Robert Markham, C.B.; George Edward Paget, M.D., D.C.L., LL.D.; George West Royston Pigott, M.A., M.D.; Osbert Salvin; Hon. John William Strutt; Henry Woodward; James Young.

AFFINITY OF HYDROGEN TO THE METALLOIDS.

In *Poggendorff's Annalen* (Nos. 2 and 3, 1873), Julius Thomsen, of Copenhagen, gives an account of somewhat elaborate researches on the affinity of hydrogen to the metalloids chlorine, bromine, iodine, oxygen, sulphur, nitrogen, and carbon.

The affinity of chlorine to hydrogen he determined directly; those of bromine and iodine through decomposition of aqueous solutions of bromide of potassium and iodide of potassium by means of chlorine. It was necessary here to determine the absorption-heat of hydrochloric, hydrobromic, and hydriodic acids.

The affinity of hydrogen to oxygen, in water, was determined by direct burning of oxygen in hydrogen; that of hydrogen to sulphur through the reaction of sulphuretted hydrogen with iodine. The absorption-heat of sulphuretted hydrogen he had previously ascertained.

Next, the affinity of hydrogen to nitrogen, in ammonia, was determined through decomposition of solution of ammonia by means of chlorine, the absorption-heat of ammonia being at the same time also determined.

As regards hydrogen and carbon, previous observers were pretty much at one in the case of marsh-gas and æthylene, and Herr Thomsen gave special attention to acetylene, about which no researches have been published. He determined, however, the heat of combustion of æthylene, from which the heat of combination can be deduced.

We do not here stay to describe the apparatus Herr Thomsen constructed for his experiments, but limit ourselves to a statement of the chief numerical results, and the deductions made from them.

And, first of all, the following table gives the affinities in the various cases specified :—

HCl	=	22001	
HBr	=	8440	
HI	=	-6036	
H ₂ O	=	68357	
H ₂ S	=	4512	
H ₂ N	=	26707	
H ₄ C	=	20420	} Where C
H ₄ C ₂	=	-10880	
H ₂ C ₂	=	-55010	} graphite.
H ₄ C'	=	23780	
H ₄ C' ₂	=	-4160	} denotes
H ₂ C' ₂	=	-48290	

From this it appears that the affinity of hydrogen to chlorine, bromine, and iodine, decreases in a marked way with the increasing atomic weight of these substances. In the case of chlorine it is strongly positive; less for bromine; and negative for iodine. This seems to be a general relation; for in the next natural group of the metalloids also—oxygen, sulphur, selenium, and tellurium—we have, for the first two members, 68357 c. and 4512 c.; and, from M. Hautefeuille's researches, it appears that the affinity in seleniuretted hydrogen is negative, showing a close correspondence in these three with the first three—chlorine, bromine, and iodine.

In the third natural group—nitrogen, phosphorus, arsenic, antimony, and bismuth—the affinity of hydrogen to the first, nitrogen, is positive, *viz.*, in ammonia, 26707 c. That, in the others, the affinity decreases with the increasing atomic weight, appears from the properties of their several hydrogen combinations; they are all easily decomposed by heat, arseniuretted hydrogen more easily than phosphuretted hydrogen, and still more easily anti-moniuretted hydrogen (decomposed even at ordinary temperature); while there is no known combination between bismuth and hydrogen, probably on account of high decomposability. Doubtless, therefore, in this group also, the same thing holds good.

In the carbon group, the affinity in the case of the first member, CH_4 , is 20420 c., or strongly positive; that it is considerably less in the next, silicium, may be inferred from the behaviour of siliciuretted hydrogen; while, with the higher members, tin and platinum, no such compounds occur. Thus, in all the four groups, the law may be said to hold.

Examining a little more closely the halogen group, we do not perceive, between the first three numbers in the above column a simple relation. The difference between the first and second is 13561 c., while that between the second and third is 14476 c. (not very far apart from the other). But the three numbers are not directly comparable with each other, because chlorine, bromine, and iodine are not found in the same aggregate state. To estimate the affinity for all the three substances in the gaseous state, we should add to the last two numbers the latent heat of transformation into gas. Doing so, we have the numbers 22001 c., 120090 c., -2986 c., the differences becoming 9911 c. and 15076 c. These numbers are more irregular than the former, so that bromine does not now stand about midway between chlorine and iodine. Indeed—

$$\begin{aligned} 9911 &= 2 \times 4956 \text{ c.} \\ 15076 &= 3 \times 5025 \text{ c.} \end{aligned}$$

which factors might, perhaps, be taken as identical, on account of uncertainty in determination of the latent heat of iodine, but it is difficult to say whether this relation is more than an accident.

It appears, then, from these (and other) comparisons, that bromine, with reference to the affinity for hydrogen, stands very much nearer to chlorine than its atomic weight (almost midway between those of chlorine and iodine) might lead us to expect.

Consider, next, the numbers in the above table expressing the affinity between carbon and hydrogen. If we take the first group, in which carbon is in the form of graphite, we have—

From this it appears that the formation of the first of these hydrocarbons is accompanied with a marked absorption of heat. We might be inclined to say that the affinity of carbon for hydrogen was *negative*; it is found, however, that hydrogen, in uniting with the already-formed lower hydrocarbons, causes a considerable development of heat. Thus—

And there can be no doubt that the affinity between carbon and hydrogen is, in fact, *positive*, as appears, also, from the determination $\text{CH}_4 = +20420 \text{ c.}$ How is this peculiar relation of carbon to hydrogen to be explained? And what is the cause of the remarkable phenomenon, that carbon appears inactive towards hydrogen, even at a high temperature, so that, only at the highest known temperature, under the influence of the electric spark, does it unite with hydrogen, with absorption of a considerable quantity of heat; that, once united with hydrogen, however, in the form of acetylene, the affinity to hydrogen appears unsatisfied, so that further quantities of hydrogen readily unite with acetylene, and that with development of heat?

If we consider the general behaviour of carbon we shall find that that has its type in this phenomenon. Carbon combines with no element at ordinary temperature; it always needs a high temperature for such combination, where possible. Thus, oxygen and sulphur combine directly with hydrogen only at a high temperature. With the remaining metalloids no direct combinations are obtainable, even at very high temperatures (with exception of hydrogen, now considered). Once combined with these

other substances, however, the carbon readily enters into other combinations. Thus, *e.g.*, carbonic oxide readily combines with oxygen into oxalic acid and carbonic acid; with chlorine, into oxychloride of carbon; with hydrate of sodium, into formic acid, &c.

In agreement with this behaviour is the fact that the formation of carbon combination, is always, with one exception, accompanied by absorption of heat. Examples are—the formation of sulphuret of carbon, of cyanogen or carburetted nitrogen, of acetylene or carburetted hydrogen. The only exception is oxygen, in the combination of which with carbon heat is developed, even when the lowest oxidation product, carbonic oxide, is formed. On further comparison of these heat phenomena, however, the behaviour towards oxygen will be found only an apparent exception. We have—

Thus, while the first atom of oxygen which combines with carbon only develops 26800 c., the heat development of the second oxygen atom, which changes the carbonic oxide into carbonic acid, is about two and a half times as great. From all that has been learned as to the oxidation of other substances, we must suppose that the first oxygen atom gives the greatest, and the following give a smaller, heat development; whereas, here the reverse occurs, and we may therefore infer that, were the affinity of carbon to hydrogen generally not so great as it is, the first oxidation product here also would appear with a seemingly negative affinity.

The entire behaviour of carbon may be explained if we consider that, whether in the form of charcoal, graphite, or diamond, it is in an inactive or passive condition, out of which it must be brought before it can enter into combination with other elements, and that an expenditure of force is required for this. The data hardly permit of determining accurately the force which is necessary; it appears, however, to be about 70000 c. for each atom of carbon.

PROCEEDINGS OF SOCIETIES.

CHEMICAL SOCIETY.

Thursday, June 5, 1873.

Dr. ODLING, F.R.S., President, in the Chair.

THE list of visitors having been announced, and the minutes of the previous meeting read and confirmed, Mr. W. H. Greenwood was formally admitted a Fellow of the Society. The following names were then read for the first time:—Messrs. Edward Collins, William Charles Young, George Bult Francis, John Turner, and William Edward Porter.

The first paper read was entitled "*The Dioxides of Calcium and Strontium*," by Sir J. CONROY, Bart., M.A. After alluding to the circumstance that, although the existence of the peroxides of calcium and strontium had been announced by Thenard in 1817, no account of them had been published since then, the author stated that lime and strontia, unlike baryta, do not absorb oxygen at a high temperature. When, however, an aqueous solution of sodium peroxide is added to a solution of a strontium salt, a hydrated peroxide of strontium is precipitated in crystalline scales, having the composition $\text{SrO}_2 \cdot 8\text{H}_2\text{O}$. The author has also obtained hydrates containing 10 and 12 molecules of water respectively. All these hydrates lose their water at 100°, leaving strontium peroxide, SrO_2 , in the form of a white powder. The hydrated calcium peroxide, $\text{CaO}_2 \cdot 8\text{H}_2\text{O}$, prepared by adding excess of lime-water to a solution of sodium peroxide acidulated with

nitric acid, is similar in appearance to the corresponding strontium compound, and, like it, loses its water at 100°, leaving the anhydrous calcium peroxide as a pale buff-coloured powder.

The PRESIDENT said the thanks of the Society were due to the author for having so satisfactorily established the existence of these dioxides. The action of an acidulated solution of sodium peroxide appeared to offer a facile method for their preparation.

Mr. T. WILLS then described a new ozone generator, which he stated was a modification of one in general use. Siemens's tube had the disadvantages of being difficult to construct and very liable to be broken; moreover, it became heated after being used for some time. This last objection also applied to Bean's apparatus of glass plates covered with tin-foil. Sir Benjamin Brodie, in his experiments, had employed an apparatus similar in principle to the Siemens tube, but the tin-foil surfaces were replaced by water; this worked very efficiently, but it was not easy to adapt to other pieces of apparatus. The new generator consists of a piece of glass tube as cylindrical as possible, with an annular coating of tin-foil on the exterior; in the interior is a carefully-turned brass box, slightly smaller than the glass tube, and tinned to protect it from the action of the ozone. Through this box a current of ice-cold water can be passed, so as to prevent the heating of the apparatus, the oxygen or air passing through the annular space between the box and the glass tube, which is fitted with caps and tubes for that purpose. The brass box and tin-foil coating are connected with the induction coil in the usual way. This apparatus yields large quantities of ozone with great ease, and, with the same battery power, appears to be more powerful than either of the other forms of apparatus; its cost, moreover, is small, and it is not liable to be broken. It can also easily be adapted to other pieces of apparatus, and the current of cold water keeps the apparatus cool, thus allowing it to be used for any length of time.

The PRESIDENT said he had worked with the apparatus, and could fully confirm what the speaker had said. He also drew attention to the great convenience of employing paraffin joints when working with ozone, as pointed out by Sir Benjamin Brodie, since that hydrocarbon is not attacked by it.

Mr. BEAN asked whether the author had compared the new form of apparatus with his, using the same surface, as he had found that with the same battery power a small surface gave more ozone than a large one.

Mr. TISLEY, in reply to a question of Mr. Bean as to the difficulty of obtaining large glass tubes, said that, for a large ozone apparatus, it would probably be better to use a number of comparatively small tubes worked in cascade.

Mr. W. N. HARTLEY then read a paper "*On the Behaviour of Acetamide when Heated with Sodium Alcohol.*" The author heated sodium methylate with acetamide in hopes of obtaining methylamine, but the reaction took a different course; ammonia was evolved, but no compound ammonia was produced. On repeating the experiment with sodium ethylate, no ethylamine was obtained, but ammonia was given off, and a crystalline substance resembling cholesterol formed in the solution. This, however, when examined microscopically, was found to consist merely of feathery crystals of acetamide enclosed in plates of sodium ethylate. Acetamide and sodium ethylate, even when mixed dry and heated to redness, do not yield any compound ammonia.

The PRESIDENT having thanked the author for the care and perseverance with which he had conducted his experiments,

Dr. ARMSTRONG said he could confirm Mr. Hartley's results, as a few years ago he had himself endeavoured to prepare ethylamine from sodic ethylate and acetamide, and had obtained nothing but ammonia.

The Secretary then read a paper "*On Iodine Monochloride*," by J. B. HANNAY. In preparing this substance

the author employed the usual processes, namely, passing chlorine into iodine until it becomes liquid and then rectifying the product, also by heating a mixture of iodine and potassic chlorate, and rectifying the product over potassic chlorate. He notices many curious circumstances connected with the crystallisation of this substance, which possesses a deep red colour in a liquid state, and when crystallised is "of a brilliant plumbago or iodine lustre." It melts at 24.7°, boils at 100.5° to 101.5°, and has a density of 3.263 at 0°. Its vapour density at 120° was found to be 80.27; theory, 81.2. Iodine chloride is decomposed by water, iodine being precipitated, and iodic acid and hydrochloric acid formed; the latter dissolves a small portion of iodine monochloride and prevents its decomposition. The compound was analysed, and its behaviour observed with numerous substances both elementary and compound. The author did not succeed in obtaining the iodine tetrachloride described by Kämmerer, although he made numerous experiments with that object.

Dr. ODLING said the Society was much indebted to the author for his careful investigation of this substance, which was the more interesting as it was the only known example of an electro-negative monochloride.

The next communication, "*On Triferrous Phosphide*," by R. SCHENCK, was read by the author, who prepared this substance by pouring a solution of ferrous sulphate into a flask in which phosphoretted hydrogen was being evolved by the action of potassic hydrate on phosphorus. The precipitate of ferrous hydrate at first formed, rapidly becomes grey, and finally black. After removal of the phosphorus, the iron phosphide was purified by boiling it with a solution of potassic hydrate, and subsequently with hydrochloric acid. The results of the analyses corresponded to the formula Fe_3P_2 ; the phosphorus appearing to be trivalent. The ferrous phosphide dissolves slowly in boiling acids, with evolution of gas, and in the dry state takes fire below 100°, burning to a reddish-brown powder. The author intends to apply the same method to the preparation of other phosphides.

The PRESIDENT having thanked the author in the name of the Society, a paper "*On Sulphur Bromide*," by J. B. HANNAY, was read by the Secretary. On adding bromine to sulphur in the proportions to form SBr_2 , heat is developed, and a deep red liquid formed, of density 2.629, which cannot, however, be distilled without decomposition. On exposure to the air it absorbs moisture, and crystals of sulphur are deposited which are soluble in carbon disulphide. It dissolves phosphorus with evolution of heat, but on attempting to distil the solution it explodes; this would seem to be owing to the sulphur bromide acting merely as a solvent for the phosphorus until heat is applied, when a decomposition suddenly takes place. With iodine chloride, sulphur bromide yields sulphur chloride and bromide of iodine. Its behaviour with methylated spirit, potassium, sodium, aluminium, and arsenic are also described.

The PRESIDENT, after returning thanks to the author for his communication, adjourned the meeting until Thursday, June 19, when the following papers will be read:—1. "On the Influence of Pressure upon Fermentation, part II., by Horace Brown; 2. "Researches on the Action of the Copper Zinc Couple on Organic Bodies, III.," and "On Normal and Isopropyl Iodides," by Dr. J. H. Gladstone and A. Tribe; 3. "On Cymenes from Different Sources Optically Considered," by Dr. J. H. Gladstone; 4. "On the Action of Bromine on Alizarine," by W. H. Perkin; 5. "On some Decompositions and Oxidation Products of Morphine and Codeine Derivatives," by E. L. Mayor and Dr. C. R. A. Wright; 6. "On the Decomposition of Tricalcic Phosphate by Water," by R. Warington; 7. "On a New Tellurium Mineral, with Notes on a Systematic Mineralogical Nomenclature," by J. B. Hannay; 8. "Communications from the Laboratory of the London Institution, No. XII.; On New Derivatives of Cresol," by H. E. Armstrong and C. L. Field.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Under this heading will be found an encyclopaedic list of chemical papers published abroad during the past week, with abstracts of all susceptible of advantageous abridgment. The two half-yearly volumes of the CHEMICAL NEWS, with their copious indices, will, therefore, be equivalent to an English edition of the "Jahresberichte."

NOTE. All degrees of temperature are Centigrade, unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances de l'Académie des Sciences, May 12, 1873.

Tumefaction of Obsidian when Exposed to an Elevated Temperature.—M. M. Boussingault and Damor.—Obsidian exposed to the action of fire suffers no change at a cherry-red heat, but between an orange-red and a red-white it swells up suddenly to a colourless spongy mass, not unlike pumice. At higher temperatures it resumes its vitreous state. The authors, in studying this phenomenon, find that the loss of weight per gramme in no case exceeded 0.00730 gm.; that the increase of bulk was from 200 to 700 per cent; that the emission of gases was slight, and in many cases absolutely nil; that the loss of weight was due chiefly to the escape of water and hydrochloric acid.

New Researches on Aldol.—A. Wurtz.—The author remarks that his view on the double nature of aldol as at once an aldehyde and an alcohol have been confirmed. Aldol after distillation, even when refrigerated, re-heats spontaneously; the temperature, in a receiver surrounded with ice, having been found to rise from 11° to 54° in seventy minutes. On cooling it becomes viscid. It possesses the reducing power common to the aldehydes. The author regards it as the aldehyde of β -oxybutyric acid. The paper concludes with a protest against the criticism of Kolbe.

Isomeric and Allotropic Transformations.—Troost and Hautesfeuille.—The authors bring forward a body of novel facts which establish an intimate connection between the physical phenomena of evaporation and the chemical phenomena of isomerism and allotropy. Striking analogies have been already established between the respective phenomena of condensation (of vapours) and of combination, and again between those of evaporation and of decomposition. Carbonate of lime in decomposition obeys the same laws as the evaporation of water. Since 1868 the authors have been studying the law of the phenomena of a change of state, when such change corresponds to a change of chemical or physical properties without an alteration of composition. They have assimilated these phenomena to those of dissociation, and have applied the same procedure for their measurement. They have observed a "tension of transformation." They show, as regards the decomposition of the cyanides of silver and mercury, that the proportion of paracyanogen in the residue increases with the pressure exercised by the cyanogen liberated; the transformation is limited by the tension of the gas, which depends on the temperature. This fact has led them to discover the inverse transformation of paracyanogen into cyanogen gas, which begins about 360°, and is slow even at 500°. They show also that cyamelide and cyanuric acid under the influence of heat behave like paracyanogen. Reciprocally cyanic acid in vapour is transformed into cyanuric acid, and the tensions which limit this novel phenomenon are numerically equal to those obtained in the inverse transformation. They also study the phenomena of tension, and the calorific phenomena which attend the transformation of white phosphorus into its red state. They establish a sharply-marked distinction between the tension of vapour

in a limited space, and the tension of transformation of the same body. This distinction permits us to analyse thoroughly the allotropic transformation of phosphorus. They show that the conversion of ordinary phosphorus into its liquid and its red state is quite comparable to the transformation of liquid cyanic acid into cyamelide. They show that the vapour of phosphorus acquires first its maximum tension corresponding to the temperature employed. This tension gradually lessens during the formation of red phosphorus, and attains a constant value—the tension of transformation at the same temperature. Phosphorus boils under ordinary atmospheric pressure at 290°. At 360° and 440° the tension becomes respectively 3.2 and 7.5 atmospheres. At 577° it had risen to 56 atmospheres.

New Process for the Proximate Analysis of Rocks.—M. Pouqué.—1 to 2 kilos. are reduced to a coarse powder ($\frac{1}{2}$ millimetre in diameter): the powder is divided into two portions, the one for mechanical, and the other for chemical examination. The former is submitted to a powerful electro-magnet set in action by 6 to 8 Bunsen elements. All the ferruginous parts are thus removed. The chemical treatment consists in the use of concentrated hydrofluoric acid for a short time. This process has been applied successfully in an examination of the lavas of Santorino.

Action of Sulphur on Arsenic.—A. Gélis.—The author has obtained the sulphides of arsenic by direct action. On heating sulphur with an excess of metal there is formed a single product, the bisulphide S_2As . It is red, opaque, and crystalline, and is distinct from the "false realgar" of commerce. With an excess of sulphur we obtain the pentasulphide S_5As . If 1 part arsenic is heated in a flask with 7 to 8 parts of sulphur the metal disappears, forming a transparent liquid, which when cooled takes the consistence of india-rubber; in time it becomes brittle. Ammonia separates it into pentasulphide, which dissolves, and free sulphur. On distillation we obtain first sulphur, then sulphur containing arsenic. The pentasulphide remains, but it is not stable, for at higher temperatures it is resolved into sulphur, and a trisulphide S_3As . The sulphide of carbon acting upon the arsenical sulphur presents curious phenomena. It abandons at first all the common sulphur which it contains, and the liquid becomes coloured. At each new treatment it removes a little sulphur without becoming saturated. Artificial realgar and orpiment are mixtures of the various sulphides of arsenic.

Action of Hydrochloric Acid Gas upon the Compound Ammonias.—Ch. Lauth.—Reserved for full insertion.

Action of the Oxygen Dissolved in Water upon Reducing Agents.—P. Schützenberger and Ch. Risler.—Hyposulphite of soda and ammoniacal cuprous oxide when in contact, in the cold and in excess, with oxygen dissolved in water, cause the latter to be divided into two portions; one of which oxidises the reducing agent, whilst the other remains in the liquid. Stannate of soda removes the whole of the dissolved oxygen. The authors believe that the oxygen remaining in the water enters into combination therewith. Thus, aerated water strongly coloured with carmine of indigo was exactly decolourised with hyposulphite. It resumed a blue colour on heating to 40°. The colour reappeared also in the cold, though more slowly. If we decolourise a second time the same phenomenon is reproduced until hyposulphite has been added enough to decolourise in the cold the same volume of aerated water. A dilute solution of oxygenated water produces the same effects.

Portable Force of Magnets.—M. J. Jamin.—The author exhibited two magnets made on his system; one weighing 6 kilograms, and carrying 80; the other (thought to be the most powerful ever made) carries about 500 kilograms, having a weight ten times less. He explains the principles on which the best possible magnet may be

constructed from plates of a given steel and length. They are briefly these:—(1) The contact should conceal the entire magnetism expanded over the exterior surface of the magnet; for this a sufficient mass should be given it. (2). This mass given the surface of adherence should be reduced till one perceives an increase in the small amount of free magnetism which the application of the contact leaves on the magnet. (3). The length and breadth of the plates being determined, their number should be sufficient to cause a little free magnetism to appear on the magnet when the contact is applied. If their number is less, the limit of permanent force is not reached; if greater, nothing more is gained. (4). The armatures should be strong and well applied; their weight should not, however, be exaggerated. M. Jamin shows how on these principles he constructed the magnets in question.

The Seine; Hydrological Studies.—M. Belgrand.

Electro-Diaphanon with Continuous Motion.—M. Mercadier.—The author wished to construct an apparatus capable—(1) of dividing time into very small equal fractions; (2) of doing so continuously; (3) of conveniently registering these fractions. The instrument he made is as follows:—A tuning-fork is placed upright, and a small electro-magnet is fixed on a support opposite the face of one of its branches; which, on the other side, has fixed to it an "interruptor style" of platinum wire. The other branch has also a style which registers its movement on a rotating blackened cylinder. Between the branches is a platinum plate on a separate support; and with this plate the interruptor style comes into contact when the branches approach each other. The positive rheophore of a pile is connected with the plate; the negative with the electro-magnet. If now the plate is put in contact with the interruptor style a spark appears, the current passes, the diaphanon begins to vibrate, and the interruptor style synchronously with it. The distance of the plate is varied till the maximum amplitude of vibration is obtained. This instrument is said to work very satisfactorily.

Observations Relative to the Notes of M. du Moncel and of MM. Thenard on the Decomposition of Carbonic Acid by the Electric Effluve.—M. J. G. Jean.

Observations Relative to a Communication of M. du Moncel on the Condensed Effluve of the Induction Discharge.—M. Houzeau.—The writer calls attention to his simple-action and double-action *ozonisers*, omitted from M. du Moncel's description of apparatus for experiments of this kind.

Modification of the Optical Saccharimeter.—M. Prazmowski.—Soleil's instrument requires considerable perfection in the visual organ to appreciate exactly the uniformity of colouring in the two halos of the field; and, in view of this, some have sought to improve on it by making the observation depend on perceiving a slight difference between two luminous intensities. M. Frellet and M. Cornu have suggested means of effecting this. M. Prazmowski's method is to use a bi-plate of spar (in place of Soleil's plate with two rotations), the face of separation being placed in the principal section of the prism. He utilises Soleil's compensator.

Spring Frosts and Winter Frosts.—M. Martha Beker.

May 19, 1873.

New Observations concerning the Influence of Metallic Deposits upon Zinc in presence of Acids and Bases.—New Processes of Heliography.—M. C. Gourdon.—Zinc, coated with certain metals, becomes exceedingly liable to be attacked by reagents. Thus, if a sheet of this metal is coated in part with a thin layer of pulverulent platinum, it is capable of being attacked by sulphuric acid diluted with 7000 vols. of water. If the platinum is replaced by gold, the zinc can be dissolved by sulphuric acid diluted with 5000 times its volume of water. Copper causes action up to 4000 volumes, silver to 3500,

tin to 1500, antimony to 700, bismuth to 500; mercury does not react similarly. If placed upon the zinc in the form of a salt it produces a spot which gradually extends itself. The solution of the zinc is most active on the margin of the spot. The soluble arsenites, arseniates, and antimonates give spots variable in appearance. They promote the solution of the zinc, but more feebly. Cobalt, nickel, and iron resemble platinum in the intensity of action they occasion when deposited upon zinc. Cobalt renders zinc soluble in sulphuric acid diluted with 10,000 volumes of water. Salts of the same base, with different acids, do not behave identically. Chlorides yield more energetic deposits than sulphates, and these, again, than nitrates. Salts rendered alkaline by the addition of a trace of ammonia give more energetic deposits than the same salts used alone. Some salts which produce no deposit when used alone give very energetic ones when previously treated with ammonia, e.g., potosulphate of iron. The most active salts are those whose saline solutions give, with ammonia, precipitates soluble in excess. Zinc covered with metallic deposits is also easily attacked by alkalies. The author considers that the rugosity of the zinc plays a more important part in these phenomena than electricity. By utilising these reactions, the author has devised two methods of photographic engraving.

Action of Ammoniacal Gas upon Nitrate of Ammonia.—F. M. Raoult.—If a stream of dry ammoniacal gas is passed over crystalline nitrate of ammonia, the salt fuses and the gas is absorbed. This phenomenon takes place at ordinary pressure, and at all temperatures from -15° to $+25^{\circ}$. The liquid, on exposure to the air, loses a part of its ammonia, and deposits crystals containing 1 equivalent of the gas united to 1 of the salt. These crystals continue to lose ammonia till pure nitrate of ammonia remains. An aqueous solution of ammonia dissolves much more nitrate of ammonia than does pure water.

Preparation and Properties of Oxymaleic Acid.—E. Bourgoin.—The new acid differs from maleic acid by 2 equivalents of oxygen, and from malic acid by 2 of hydrogen.

Maleic acid		$C_8H_4O_8$
Oxymaleic acid		$C_8H_4O_{10}$
Malic acid		$C_8H_6O_{10}$

To obtain this acid, the author prepares monobromomaleate of baryta, and precipitates the baryta by sulphuric acid. The monobromomaleic acid thus obtained is saturated with a dilute solution of caustic potassa. The solution of the neutral salt is stirred up in the cold with oxide of silver well washed and recently prepared. The bromine is separated as bromide of silver, and oxymaleate of potassa remains. The filtrate is precipitated with acetate of lead, and the oxymaleate of lead, after washing, is decomposed with sulphuretted hydrogen. The acid is evaporated to dryness and re-dissolved in ether, when it appears in the form of fine elongated crystals arranged in stellar groups. It is white, solid, resembling malic acid in taste, and very soluble in water, alcohol, and ether. It is a bibasic acid.

Acid Derivatives of Naphthylamine.—D. Tommasi.—Naphthylacetamide—

This body represents acetamide in which 1 atom of hydrogen is replaced by naphthyl, $C_{10}H_7$, and is formed by the action of chloride of acetyl or glacial acetic acid upon naphthylamine. It is prepared by heating 1 part of naphthylamine with 4 parts of crystalline acetic acid to the boiling-point for five to six hours in a cohobator. The contents of the vessel are then poured into cold water, when naphthylacetamide is precipitated. It is thrown on a filter, washed, and re-crystallised from boiling alcohol. It forms white, silky needles, melting at 152° , and capable of sublimation at 160° . It is insoluble in

cold, and sparingly soluble in boiling water; very soluble in hydrochloric, acetic, and dilute sulphuric acids. It does not become coloured on exposure to the air, nor when treated with chromic acid or chloride of lime.

Naphthyl-chloracetamide—

This body differs from the former by the substitution of 1 atom of chloracetyl for 1 atom of acetyl, and is prepared by the reaction of chloride of acetyl upon naphthylamine. It forms silky needles, colourless, fusible, and sublimable at 161°, insoluble in water, but soluble in hot alcohol and acetic acid. It gives no colour with chromic acid and chloride of lime.

Chlorides of Propylene.—E. Reboul.—The normal chloride, $\text{CH}_2\text{Cl}-\text{CH}_2-\text{CH}_2\text{Cl}$, is the homologue of chloride of ethylene, $\text{CH}_2\text{Cl}-\text{CH}_2\text{Cl}$, or the so-called "Dutch liquor." It has a pleasant odour, and boils at 117°; its density is 1.201 at 15°. Alcoholic potassa, when hot, removes from it hydrochloric acid and changes it into chloride of allyl, and finally into ethyl-allylic ether. Chloro-propylol, $\text{CH}_3-\text{CH}_2\text{CHCl}_2$, is the true homologue of the chloride of chlorated ether, CH_3CHCl_2 . Bromides of propylene are known, corresponding to three of the chlorides. The fourth, bromopropylol, might doubtless be formed by the action of perbromide of phosphorus upon propylic aldehyde. The author announces his intention of examining the chlorobromides of propylene.

Note on the Solar Cyclones, with a Reply from M. Respighi to MM. Vicaire and Secchi.—M. Faye.—M. Respighi, in his letter, asserts the excellence of his telespectroscope (called in question by P. Secchi). The chromosphere may appear, as P. Secchi says, more elevated where the spots are by a simple effect of perspective, the surrounding faculae being projected on each other; but having carefully watched the progress of the spots in periods of quiet especially, he (M. Respighi) had often observed depression at the spot, the red layer being almost interrupted. He also urges that the rarity of reversal of spectral lines in the nuclei is a proof of the small thickness of the chromosphere there; if it were as thick and as largely mixed with luminous jets as neighbouring parts one should be constantly seeing a reversal of the lines. The reversal when observed is doubtless due to the projection of an intense jet or protuberances on the spot. M. Faye remarks on the complexity of the spot phenomena; including faculae, jets emanating from them, depression at spot axis, the spot itself, and the solar rotation causing it, all in mutual dependence.

Note on the Mechanical Properties of Different Bronzes.—M. Tresca.—The writer arrives at the conclusion that there are bronzes more homogeneous, ductile, resistant, and elastic than those produced in the State foundries; and he calls on the Artillery Department to examine the products of private works so as to determine the bronze most serviceable for cannon.

Electro-Diapason with Continuous Movement.—Second note by M. Mercadier.—(The first appears in the previous page.)—Numerical results are cited as showing that the vibrations are synchronous, notwithstanding the intermittent action of the electro-magnet. The amplitude of the vibrations depends on the form of diapason, on the distance of the electro-magnetic poles from it, on the height at which the magnet stands, on the intensity of the current, and on the nature and length of the style.

Experiment in Electro-Dynamics.—MM. Planté and Niaudot-Breguet.—If a secondary couple (of lead plates) be charged with a Gramme magneto-electric machine, and then be left undischarged in connexion with the machine which has been stopped, the latter presently begins to turn under influence of the current from the secondary couple in the same direction as it was turned

in charging; and continues turning (more slowly, indeed, yet at a considerable rate) for two or three minutes till the couple is discharged. In this restitution there is, probably, only slight loss. That the machine in its motion should turn in the same direction as before seems paradoxical, but may be explained by the laws of currents. Further, the secondary couple once charged gives a current more powerful than that produced by the machine which it puts in motion, the difference of intensities continuing the motion.

Remarks on some Peculiarities Observed in Researches on Spectrum Analysis.—L. Lecoq de Boisbaudran.—In passing the induction spark between two metallic pieces the spectral lines are chiefly or exclusively obtained at the negative pole; but with aluminium the contrary occurs. Certain solutions examined with the spark only give the air spectrum, even when negative; by moistening the exterior platinum wire this may be avoided. The presence of metallic molecules in the inter-polar space enfeebls the air spectrum. The exterior wire may be brought nearer the solution when the latter is positive than when it is negative, in the latter case the liquid tends to meet the wire. The projection of the liquid in droplets; its pulverisation increases so rapidly with the length of spark, and varies with the liquid. The dilution of liquors influences the relative intensities of the lines. When, after long calcination in a gas-flame, there is hardly a trace of matter on the platinum wire; it is not always the lines originally brightest which persist longest. With the spark many metals do not give lines when in the compact state, but furnish beautiful spectra when finely divided. It would sometimes be of advantage to mix the metals with pure lead, from which the spark should be brought.

Classification of Absorption Bands of Chlorophyll.—M. Chautard.—The author divides the chlorophyll bands into three distinct categories. The first contains simply the band in the middle of the red; this he calls the *specific band*. In the second he includes all bands which have been observed in chlorophyll solutions, new or old, neutral, acid, or alkaline; these he calls *supernumerary bands*. The most remarkable is that which results from division of the specific band in the red, under the influence of alkalis. The third category comprises *accidental bands*, not having the permanent character of the preceding, and being produced in special conditions. Of this kind is that from a division of the specific band through acids. The additional band here seems to arise from the less refrangible side, while in the alkaline solution it arises from the other. The author gives several particulars as to the method of treating chlorophyll in order to obtain various bands.

Experimental Researches on the Influence of Changes in Barometric Pressure on the Phenomena of Life.—P. Bert.—Reserved for translation.

On Different Electric Movements Observed in Connection with the Interrupted Lightning Conductor of Greenwich Observatory.—M. de Fonvielle.—The writer pivoted a needle (by its centre) excentrically on a copper disc connected with the aerial rod of the conductor, and observed oscillatory movements in it, which he compares with what has been noticed by other observers.

Revue Universelle des Mines, de la Metallurgie, des Travaux Publics, des Sciences et des Arts Appliqués à l'Industrie, January and February, 1873.

Note on the Furnace of Danks.—Victor Tahon.—The author sums up the results of his examination of this furnace as follows:—The apparatus of Danks is a practical conception, capable of regular and prolonged employment. It suppresses the manual labour of puddling, and replaces it by a mechanical movement which is more advantageous for the purification of the iron.

The result is a reduction of the hands employed and of the expense of labour. The production is strikingly improved alike in quantity and quality.

Note on the Definition of Steel.—A. Greiner.—A mechanical paper.

On Cast Steel obtained by the Bessemer and Siemens Processes.—M. A. Noblet.—The author gives the following analytical results, obtained by Dr. Kezler:—

	I.	II.	III.	IV.	V.	VI.
Graphite ..	2'410	0'75	0'020	0'020	0'010	0'020
Carbon ..	0'620	2'42	3'170	1'590	0'180	0'190
Silicon ..	2'410	1'26	0'270	0'030	0'010	0'160
Phosphorus ..	0'130	0'14	0'135	0'130	0'140	0'150
Sulphur ..	0'024	0'01	0'007	0'013	0'023	0'021
Manganese ..	2'450	0'70	0'190	0'120	0'060	0'220

In this table I. gives the composition of the crude mixture before commencement; II. to V. the composition of samples taken at various stages of the process; VI. that of the finished metal. Another investigation gave—

	I.	II.	III.	IV.	V.	VI.
Graphite ..	2'52	0'140	0'040	0'010	0'000	0'000
Carbon ..	1'06	3'650	3'530	2'470	0'290	0'450
Silicon ..	1'87	1'200	0'640	0'067	0'021	0'083
Phosphorus ..	0'10	0'106	0'096	0'097	0'109	0'104
Sulphur ..	0'37	0'069	0'061	0'077	0'113	0'080
Manganese ..	1'04	0'230	0'080	0'060	0'050	0'340

I. represents the material; II. sample taken after four minutes; III. the beginning of the second period; IV. the middle of the second period; V. sample before the introduction of the spiegel; and VI. the finished metal. These analyses show the utter inability of the Bessemer process to eliminate phosphorus. The author concludes that the employment of ordinary pig-irons for the manufacture of steel is a problem yet unsolved.

Les Mondes, Revue Hebdomadaire des Sciences, par L'Abbé Moigno, Tome xxxi., No. 4, May 22, 1873.

Distillation of Petroleum-Schists.—Seguin has invented a method of effecting the distillation of these schists, in which the residues of former operations are used as fuel. The combustion takes place in a furnace of peculiar construction, placed below the retorts. In the Autun district alone this process will effect a saving of coal to the value of 1000 francs daily. The oils obtained are of fine quality, and the yield appears to be augmented.

Preservative against Rust.—Common mercurial ointment is found to be remarkably efficacious in preventing the formation of rust upon articles of iron and steel, such as gun-barrels.

Preservation of Alimentary Substances.—Dr. Sacc.—After a series of experiments, carried on uninterruptedly since 1845, the author has come to the following conclusions:—(1). That organic bodies decompose spontaneously, each in a different manner, either with or without access of air, and either with or without the intervention of microscopic animal or vegetable beings. (2). There is only one certain method of preserving organic substances,—that is by removing their vital moisture, totally or in part, by means of a salt which by remaining in their tissues may hinder the entrance of atmospheric air, and prevent the attacks of insects. (3). The salt which best attains this end, as regards speed, quality of produce, and salubrity, is acetate of soda.

No. 5, May 29, 1873.

On Hofmann's Direct Vision Spectroscope.

On Jules Dubosq's Penumbral Saccharimeter.—These two papers would not be intelligible without the accompanying diagrams.

PATENTS.

ABRIDGMENTS OF PROVISIONAL AND COMPLETE SPECIFICATIONS.

Improvements in the manufacture of bleaching-liquor. Henry Deacon, alkali manufacturer, Widnes, Lancashire. November 7, 1872.—No. 3309. Bleaching-liquor is usually formed by causing a mixture of caustic lime, and water to absorb chlorine, and the reaction may be represented by the following formula:—

but if the caustic lime be replaced by carbonate of lime, then the reaction may be represented as follows:—

and the result may be described as a mixed solution of chloride of calcium and hypochlorous acid, with liberation of carbonic acid. This solution may be used for bleaching purposes instead of the ordinary bleaching-liquor, or it may be used for the production of pure chlorine by the addition to it of hydrochloric acid, or it may be converted into ordinary bleaching-liquor by the addition of caustic lime, as shown in the following formula:—

Now my invention consists in using certain kinds of carbonate of lime to replace wholly or in part the caustic lime usually employed. One of the kinds of carbonate of lime I employ is that procured in a state of fine division by causticising solutions of the carbonates of soda or of potash. This finely divided material is usually a mixture of caustic lime with carbonate of lime, and may be used with water instead of caustic lime, and be impregnated with chlorine in the usual bleaching-liquor making apparatus, too well known to need description. The other kind of carbonate of lime I employ is chalk or limestone in lumps. I fill towers, or columns, or other vessels constructed of stone or other suitable materials, with such lumps of chalk or limestone, which are continually moistened with water, or with weak liquor produced in the course of the manufacture, and I pass chlorine gas or gas containing chlorine through the apparatus amongst the lumps of chalk or limestone. Carbonic acid gas is evolved and escapes, and a solution is obtained which may be described as containing free hypochlorous acid and chloride of calcium, which can be used as a bleaching-liquor, or it may be used for the production of pure chlorine by the addition to it of hydrochloric acid, or be converted into ordinary bleaching-liquor by the addition of lime as before described. This improvement is especially applicable to the manufacture of bleaching-liquor by the aid of chlorine gas when mixed with carbonic acid gas, or otherwise diluted.

Improvements in the manufacture of salts and oxides of lead and in apparatus therefor. William Marriott, manufacturing chemist, Huddersfield. November 8, 1872.—No. 3322. My improved apparatus for reducing the lead to powder is constructed somewhat on the principle of the "Gifford" injector. My apparatus for converting the lead powder into carbonate of lead has a cylinder with an agitator fixed on a vertical central hollow shaft connected with a pipe whereby steam air and carbonic acid are admitted to the said shaft and to the agitator. The cylinder is supplied with water, and as the lead rises to the surface of the water it passes away through suitable exit pipes in the form of carbonate of lead.

Improvements in the manufacture of stearic acid. Alexander Melville Clark, patent agent, 53, Chancery Lane, Middlesex. (A communication from Edouard Deiss, of Marseilles, France). November 8, 1872.—No. 3323. The invention consists in the application of sulphuret of carbon or other solvent producing similar results for increasing the fluidity of the oleic acid contained in fatty acids so as to facilitate its separation from stearic acid in a cold state without the use of hot pressure as heretofore. The invention is also applicable for extracting the margarine from the residues of all kinds of animal and vegetable oils, and also for the preparation of oleine from tallow for lubricating purposes.

An improved process of tanning hides and skins. Charles de Sainte Marie, doctor, Port Ste. Marie, France. November 9, 1872.—No. 3335. This invention consists—First. In the employment of solutions of the salts of ammonia, such as the chloride, acetate, azotate, and oxalate, but especially the sulphate, for the purpose of neutralising the alkalies used for removing the hair. Secondly. The employment of combined solutions of sulphate of soda and sulphate of ammonia for cleansing, preparing, and de-alkalising mucous, papillary, or other membranes.

Improved apparatus to be used in the treatment of sewage deposits and other like substances. Major-General Henry Young Darcock Scott, C.B., Baling, Middlesex. November 11, 1872.—No. 3355. This apparatus consists of a drying floor of a corrugated or indented form, but with the elevations on the upper side so sloped as not to allow of permanent lodgments of matter upon them. In the hollows on the upper side archimedean screws are kept in rotation, and by so doing they constantly thrust forward the material to be dried.

Improvements in the treatment of human faecal matters, and in the apparatus or means employed therein. James Alexander Manning, Inner Temple, London. November 11, 1872.—No. 3356. This invention consists:—First. Of a mode of assisting heating the tank employed for evaporating faecal matters described in the Specification of the Patent No. 2269, A.D. 1869, by utilising for that purpose the mixture of carburetted hydrogen gas and air evolved during the process of evaporation. Secondly. In introducing steam into the evaporating

chamber through the shaft of the agitator, which is made hollow and is perforated on its under side for that purpose. Thirdly, Of an improved arrangement of water-closet, whereby the fecal matters are discharged into a separate vessel in lieu of into the sewer, the water employed for flushing the closet being alone discharged into the sewer.

NOTES AND QUERIES.

"Experiments with the Torsion-Rod for Determining the Mean Density of the Earth," forming vol. xiv. of the *Memoirs of the Royal Astronomical Society*. By Francis Baily, Esq., Vice-President of the Society. London. 1843.

P. 71.—A series of 44 experiments mentioned on this page "seem to indicate that it is the lightness of the balls that causes the discrepancies noticed on the recent occasions."

"I made 36 experiments in this manner" [with ivory balls]; "and found that the discordances were still more considerable than any which I had ever yet experienced with other balls, not only in the positions of the resting point, but also in the time of vibration. In fact, the experiments made on January 17, are so anomalous, that I have been obliged to divide them into three portions."

P. 72.—"The experiments made on January 20th exhibit similar irregularities. . . . The six remaining experiments on this day present so many anomalies that the results are not entitled to much credit. For, the arc of vibration, in experiments 1539 and 1543, increased instead of being diminished; which evidently showed that some unlooked for disturbing force was in active operation, which affected with great irregularity both the time of vibration and the march of the resting point."

P. 72.—" . . . there is sufficient discrepancy to show that these light balls" [ivory] "are not the best adapted for giving uniform results, whether suspended by silk or iron."

"The experiments on January 28 assimilate to those made on January 20, inasmuch as there is great irregularity in the time of vibration and in the march of the resting point; and likewise in the circumstance that the arc of vibration, in experiment 1598, increased instead of being diminished, and that the last of the single results is very discordant."

P. 73.—"Not being able by these proceedings to throw any light on the cause of the discrepancies so frequently met with in these cases, I conceived it might be occasioned by a slight twisting of the suspension lines: for on a close examination of the lines which were now in operation, I observed that they were not exactly in the same vertical plane, there being nearly 30° difference between the upper and lower positions."

P. 74.—"As I was desirous of ascertaining the true cause of the discordances that still existed at every slight change of the apparatus, I resolved on pursuing some further experiments with different balls, where no other alteration whatever (except the change of the balls) should be made in the arrangement or disposition of the apparatus."

P. 75.—" . . . These 60 experiments . . . afford satisfactory evidence that, when the same mode of suspension is adopted, the slight differences that arise are principally caused by the difference in the weight of the balls successively attached to the torsion-rod. Other causes of difference, however, may be suspected to arise from a variation in the mode of suspension."

P. 77.—"It must be confessed that the results, with these light balls, have not in general been so accordant as those obtained with the heavier ones."

P. 78.—" . . . those anomalies which, however trifling in their effect upon the general result, evidently showed that some disturbing force was in operation that had hitherto escaped detection. The discordances most difficult of solution were those that occurred when the light balls were employed; more especially when the ivory balls were used."

MEETINGS FOR THE WEEK.

Analysis of Food, Water, and Air.—Mr. WANKLYN has opened a Laboratory at 177, Charlotte Street, Fitzroy Square, and is prepared to give Practical Instruction in Chemical Analysis to Medical Officers of Health, and to persons proposing to undertake the duties of Public Analysts under the new Act.

PRACTICAL CHEMISTRY.

Laboratory, 60, Gower Street, Bedford Square, W.C.

Mr. Henry Matthews, F.C.S., is prepared to give instruction in all branches of PRACTICAL CHEMISTRY, particularly in its application to MEDICINE, AGRICULTURE, and COMMERCE.

The Laboratory is open daily, except Saturday, from ten to five o'clock; on Saturday, from ten till one o'clock.

Mr. Matthews is also prepared to undertake ANALYSES of every description.

For Particulars and Prospectuses, apply to Mr. Henry Matthews, the Laboratory, 60, Gower Street, Bedford Square, W.C.

Royal Polytechnic Institution, 309, Regent Street.—Laboratory (entirely re-fitted) and Class-Rooms are now open.

ASSAYS, ANALYSES and Investigations connected with PATENTS conducted.

Pupils received for Class and Private Study. Special facilities are offered to persons preparing for GOVERNMENT EXAMINATIONS.

Classes are now forming for Practical Study in CHEMISTRY STEAM, and PHYSICS.

For particulars, apply to Professor E. V. GARDNER, F.A.S. M.S.A. at the Institution.

BERNERS COLLEGE of CHEMISTRY.—

EXPERIMENTAL MILITARY and NAVAL SCIENCES, under the direction of Professor E. V. GARDNER, F.E.S., &c., of the late Royal Polytechnic Institution and the Royal Naval College.

The Laboratory and Class Rooms are open from 11 to 5 a.m., and from 7 to 10 p.m. daily.

Special facilities for persons preparing for Government and other examinations.

Private Pupils will find every convenience.

Analyses, Assays, and Practical Investigations connected with Patents, &c., conducted.

For prospectus, &c., apply to Prof. E. V. G., 44, Berners-street, W

THE LIVERPOOL COLLEGE OF CHEMISTRY, 96, DUKE STREET, LIVERPOOL.

Specially Devoted to the Study of CHEMISTRY, TECHNOLOGY and ASSAYING.

Laboratories open throughout the Year.

MARTIN MURPHY, F.C.S., &c., Principal (Successor to the late Dr. SHERIDAN MURPHY).

A Special Laboratory is devoted to Commercial Analyses of every description, and to Mineral Assays.

Manufacturers' and Smelters' Analyses and Assays undertaken on Contract.

Patentees and Inventors Advised and Assisted. Works and Mines Inspected. The Erection of Manufacturers' Plant Supervised, &c.

Terms and Fees VERY MODERATE.

Further Particulars and Full Prospectus on application to The Principal, MARTIN MURPHY, F.C.S. &c.

ON PHENOLCYANINE.

By T. L. PRIPSON, F.R.D., F.C.S., &c.

THIS new substance is derived from phenol, and appears to me to possess considerable interest, from the analogies it presents with certain colouring matters derived from lichens, and inasmuch as it may perhaps throw some light on the constitution of indigo. It is obtained directly from phenol by dissolving the latter in alcohol, adding liquid ammonia, and allowing the mixture to remain for some weeks in a partially-closed flask; but, in about fifteen days, when the liquid has become a rather dark green, twice its volume of water and one quarter of its volume of ammonia are added, and the mixture is left to itself for about six weeks. By this time the liquid has taken a very fine blue tint, very dark, and a certain quantity of phenolcyanine is found at the bottom of the vessel and adhering strongly to the glass. That which remains in solution can be collected by saturating the liquid with salt. The product is thrown on a filter, and the new substance dissolved in hot alcohol or benzol, from which it is obtained by evaporation.

Properties.—Thus obtained, phenolcyanine is a resinous substance of a very dark blue, nearly black, and showing metallic copper-coloured reflections like indigo. In alcohol, it forms a fine deep blue solution, in ether a reddish purple-blue, and in benzol a reddish purple solution. Concentrated sulphuric acid dissolves it easily, forming a bluish green liquid; hydrochloric acid has little action; and nitric acid forms a nitrous compound very different from picric acid. Phenolcyanine is very slightly soluble in water, but dissolves in hydrated alcohol to which ammonia is added, and this solution can be considerably diluted with water. These alkaline solutions are deep sky-blue by day, but of a vinous red by night or when a flame is seen through them. Acids redden these solutions, and alkalis bring back the blue, as with litmus. Nascent hydrogen reduces phenolcyanine, and renders it completely colourless, but when the solution remains exposed to the air in presence of ammonia the blue colour soon returns. A mixture of ferrous sulphate and lime does not destroy the colour of phenolcyanine as it does that of indigo-blue; so that the former rather resembles the coloured derivatives of orceine than it does indigo. Phenolcyanine melts very easily, and can be partially volatilised in purple vapour; the remainder is decomposed, and leaves a porous charcoal.

Composition.—My analyses of this new product have not been very satisfactory, on account of the very small quantity which I have yet had at my disposal for this purpose; I believe, however, that I can assign to it the formula $C_{12}H_7NO_2$, or $C_{12}H_7NO_4 = C_{12}H_5NO_2 + 2HO$. According to the most recent analyses, orceine is $C_{14}H_7NO_6$, and indigo-blue $C_{16}H_3NO_4$, so that it is possible both may some day be formed from phenolcyanine. I hope to be able soon to refer to its composition again.

COLORIMETRIC ANALYSIS.

By GEORGE E. DAVIS.

IN the CHEMICAL NEWS, vol. xxvii., p. 262, Mr. Sidney Harvey has devised a colorimeter very similar to one devised by myself, which I have had in constant use for over three years; in fact, Mr. Harvey's instrument is almost an exact counterpart of my original colorimeter,

which I was obliged to modify completely before I could depend upon its indications.

The above is an engraving from a photograph of the colorimeter as it is now in use. I may describe it thus:—It consists of a mahogany box, 6 ins. by 3 ins., and 1½ ins. deep, into which can be inserted two white glass tubes with flat bottoms. The tubes themselves are 6½ ins. long, and ½ in. in diameter; the holes upon which they rest are ¾ in. in diameter; and half of the foot-board is cut away to ¼ in., in order to admit and to steady the tubes. The tubes are placed 1½ ins. from centre to centre, and between the tubes is a scale, preferably graduated into millimetres. The tops of the tubes are held in position by the top of the case, being made so that half takes away; then the tubes are easily abstracted for emptying, cleaning, &c. Now above the tubes is a mirror swinging upon a pivot on each side, which serves to throw the light down the tube, and below is a similar mirror for observation.

If the tubes are now partly filled with standard ammonia which has been Nesslerised, and if the light be thrown up the tubes, we shall see a great deal of the white glass in the top mirror, which prevents to a great extent the exact colour being obtained; and the greater the difference in

level of the liquid in the tubes, the greater the amount of interference in the tint.

Nor is this all to be guarded against, for the tubes ought to be made of the same glass to give accurate results. This fact manifested itself to me in December, 1870, when one of the tubes was broken, and before using the colorimeter, whatever tubes are employed, it should be tested by filling the tubes to an equal height with a coloured liquid, when, of course, the discs upon the mirror should be identical. My instrument is always used in a vertical position, the top mirror throwing the light through the tubes down upon the bottom mirror; the bottom of my tubes are flat, and the size of the mirrors 3 ins. by 2½ ins.

My method of procedure is nearly similar or it may be styled identical with Mr. Sidney Harvey's. It is thus— I take 100 c.c. of the solution in which the ammonia is to be determined, add Nessler, shake, and allow to stand for a quarter of an hour. With this solution I fill one of the tubes half-full, and notice the tint on the mirror below. I then make a solution to correspond as nearly as possible (with my standard ammonia) to the solution in the other tube, and enter it in the note-book as containing x milligrammes of ammonia in a litre. This solution, 100 c.c. of which have been Nesslerised, is then added in the empty tube by a fine pipette until the discs appear the same below. Now, supposing the unknown solution stood at a height of 37 m.m. in one tube, and the standard solution in order to obtain the same tint was added until 49 m.m. was reached; then, if this standard solution, contained

0.7 milligramme in a litre, the quantity of ammonia in the unknown solution would be—

$$\frac{0.7 \times 49}{37} = 0.92.$$

I first arranged this apparatus in June, 1870, and did a deal of work with it in water analysis until February, 1871. In March, 1871, it was used in a series of experiments upon the estimation of carbon in cast-iron, and since then it has been used by several chemists in different researches where quantitative determination by depth of colour could be performed.

Walsall, June 11, 1873.

INFLUENCE OF OPTICALLY-INACTIVE SOLVENTS ON THE ROTATORY POWER OF OPTICALLY-ACTIVE SUBSTANCES.

THIS subject is discussed by Dr. A. C. Oudemans in a recent number of *Poggendorff's Annalen*.

Reviewing the work of previous observers, he states that Biot, having found (simultaneously with Seebeck), in the year 1815, that circular polarisation was obtainable from a liquid of organic origin, viz., oil of turpentine, was led to a series of researches, from which it appeared that many other liquids, both purely organic compounds, and solutions of solid organic substances in some inactive liquid, gave the phenomenon in varying measures. For use of comparison, in studying the laws of circular polarisation, Biot adopted the expression *specific or molecular rotatory power*, meaning thereby (for a determinate ray of light) the turning of the plane of polarisation, caused by a layer of the active substance 1 decimetre thick, having a degree of concentration = 1, and a density = 1. Hence, if α denote the directly-observed turning of the plane, for a layer l decimetres thick, of a simple solid or liquid combination whose density is δ , the specific rotatory power (a) of this substance will be $= \frac{\alpha}{l \cdot \delta}$.

For solutions of active substances in inactive liquids, the formula takes the form—

$$(a) = \frac{\alpha}{\epsilon \cdot l \cdot \delta},$$

where ϵ denotes the degree of concentration, i.e., the relation between the weight of the active constituent and that of the entire liquid.

Biot inferred, from his earlier experiments, that the specific rotatory power (say, S.R.P.) of a dissolved active substance was independent of the degree of concentration; but he afterwards perceived that what he had considered a common case was the exception, and not the rule. With tartaric acid, especially, was the influence of concentration conspicuous.

It was further established, by Biot and others, that temperature had some influence on the S.R.P. of active substances in solution.

The influence of the *nature of the solvent* has been only slightly investigated. In chemical handbooks it appears to be often taken for granted that the S.R.P. is not affected by the solvent, where the latter has no so-called chemical action on the active substance. Biot and Jodin have published a few observations on the point; the former having examined the different effects, on rotatory power of tartaric acid, of water, alcohol, and wood-spirit used as solvents; while the latter found the rotatory power of inverted sugar affected differently by water and by alcohol.

Unacquainted with the influence of inactive solvents now referred to, Dr. Oudemans was accidentally led to study the subject when examining the rotatory power of sulphate of cinchonine. Merely to facilitate solution of

the salt in water, which was taking place very slowly, he added some alcohol, not expecting this would affect the rotatory power. Several experiments thus made, with different quantities of alcohol, gave such different results, optically, as could only be attributed to the alcohol added.

In prosecuting the inquiry to which he was thus attracted, he used one of Wild's polaristrometers and the lime-light. The solutions were brought to a temperature of 17° or 18°. [Sundry other details are given as to the mode of preparing the solutions, &c.] The following table shows the principal results:—

Substance examined.	Solvent.	Degree of Concentration.	Specific Rotatory Power. Degrees.
Cane sugar ..	Water.	0.056	R 66.9
"	Alcohol 50 p.c.	0.050	R 66.4
Light cubebin oil	Unmixed.	—	L 40.8
"	Alcohol.	0.061	L 41.6
"	Benzol.	0.060	L 41.6
"	Chloroform.	0.075	L 41.7
Cinchonine ..	Alcohol.	0.006—0.008	R 228.0
"	Chloroform.	0.004—0.005	R 212.0
Sulphate of cin- chonine	Water.	0.014	R 169.0
"	Alcohol.	0.023	R 191.0
"	"	0.055	R 193.0
Nitrate of cin- chonine	Water.	0.020	R 154.0
"	Alcohol.	0.022	R 172.0
Hydrochlorate of cinchonine ..	Water.	0.016	R 162.0
"	"	0.026	R 158.0
"	"	0.031	R 156.0
"	Alcohol 93 p.c.	0.054	R 175.0
Brucin	Alcohol.	0.054	L 35.0
"	Chloroform.	0.019	L 127.0
"	"	0.049	L 119.0
Podocarpic acid	Alcohol.	0.040	R 136.0
"	Alcohol 93 p.c.	0.090	R 136.0
"	Ether.	0.040	R 130.0
"	"	0.070	R 130.0
Podocalpate of soda	Water.	0.046	R 82.0
"	"	0.064	R 79.0
"	"	0.138	R 73.0
"	Alcohol.	0.090	R 86.0
Phlorizin	"	0.046	L 52.0
"	Wood-spirit.	0.039	L 52.0

This affords sufficient evidence that, while sometimes (as in the case of phlorizin) the S.R.P. of an active substance is not perceptibly modified by the solvent; still, as a rule, the use of different solvents, in circumstances otherwise similar, produces greater or smaller differences. With cane sugar, only a slight difference is observed. The differences are very great in the case of alkaloids and their compounds. The rotatory power of brucin is, in the chloroform solution, nearly one and a half times as great as in the alcohol solution. It is possible that all alkaloids behave generally like cinchonine and brucin in this respect.

In the course of his experiments, Dr. Oudemans observed the curious fact that the S.R.P. of cinchonine in solution with mixtures of alcohol and chloroform is modified in quite a different way from what might naturally be expected from the influence of the two liquids separately. Thus, in the above table, the value of (a) for cinchonine dissolved in alcohol = R 228°; and for cinchonine dissolved in chloroform = R 212°. One might anticipate that, with mixtures of both solvents, the values of (a) would lie between these numbers, and would be greater the more alcohol there was in the mixture, and *vice versa*. It is not so, however, as the following table shows:—

No.	Composition of Solvent.		Value of (a). Degrees.
1.	100.00 p.c. CHCl ₃	+ 0.00 p.c. C ₂ H ₆ O	R 212.0
2.	99.66 " "	+ 0.34 " "	216.3
3.	98.74 " "	+ 1.26 " "	226.4
4.	94.48 " "	+ 5.52 " "	236.6
5.	86.95 " "	+ 13.05 " "	237.0
6.	82.26 " "	+ 17.74 " "	234.7
7.	65.00 " "	+ 35.00 " "	229.5
8.	44.29 " "	+ 55.71 " "	226.6
9.	27.54 " "	+ 72.46 " "	227.6
10.	17.02 " "	+ 82.98 " "	227.8
11.	0.00 " "	+ 100.00 " "	228.0

It appears, from the numbers thus obtained (and which Dr. Oudemans represents in a curve),—

(1). That, in alcoholic solution of cinchonine, about the half of the alcohol may be exchanged for chloroform without the S.R.P. of the cinchonine being notably affected. On the other hand, if, in a solution of cinchonine in chloroform, only 1-300th of the solvent be exchanged for alcohol, the S.R.P. is already altered 4°.

(2). The S.R.P. of cinchonine is about a maximum when the solvent mixture contains 10 per cent alcohol and 90 per cent chloroform.

(3). From the influence which two liquids have separately on the S.R.P. of an active substance, no inference can be drawn as to the effect of a mixture of them.

On the last account it is important, in examining the S.R.P. of active substances, to ascertain the purity of the solvent used.

Dr. Oudemans next sought to determine whether the influence of different solvents on the S.R.P. of an active substance was connected with the greater or less solvent power of liquids for the active substance. If this were the case, the S.R.P. of an active substance should probably be more modified by an inactive liquid in which it is easily dissolved, than by one in which it is dissolved with difficulty.

To test this, he determined the solubility of cinchonine in alcohol, in chloroform, and in mixtures of these liquids. The results are as follows:—

No.	Composition of Solvent.		Percentage Quantity of Dissolved Substance. (Weight of solvent = 100.)
1.	100.0 p.c. alcohol	+ 0.0 p.c. chloroform.	0.77
2.	90.9 " "	+ 9.1 " "	0.94
3.	77.6 " "	+ 22.4 " "	1.27
4.	64.9 " "	+ 35.1 " "	1.83
5.	47.7 " "	+ 52.3 " "	3.30
6.	34.9 " "	+ 65.1 " "	4.84
7.	27.4 " "	+ 72.6 " "	5.67
8.	22.8 " "	+ 77.2 " "	5.88
9.	18.2 " "	+ 81.8 " "	5.81
10.	7.8 " "	+ 92.2 " "	4.14
11.	1.9 " "	+ 98.1 " "	1.34
12.	0.0 " "	+ 100.0 " "	0.28

With these data he constructs a curve of solubility, and it appears—

(1). That the solubility of cinchonine in chloroform is smaller than in alcohol.

(2). That, starting from the two zero points, the solubility of cinchonine, with increasing quantities of chloroform, rises much less than with increasing quantities of alcohol.

(3). That cinchonine is most soluble in a mixture of 20 per cent alcohol and 80 per cent chloroform.

Comparing the curve here obtained with the former curve, they appear to resemble each other, in that both the S.R.P. and the solubility of cinchonine rapidly rise with the increase of the alcohol contents, and also that a smaller solubility of alcohol in chloroform corresponds to a smaller S.R.P. They differ, inasmuch as the maximum of solubility does not coincide with the maximum of S.R.P.,

and the substitution of chloroform for alcohol immediately modifies the solubility, but not the S.R.P.

Still Dr. Oudemans considers that the solubility and the S.R.P. of active substances stand in a certain connection. For the present, one is not in a position to explain satisfactorily the differences in the two curves; he suggests, however, that possibly, in mixture of the two liquids, other actions take place which affect the S.R.P. Thus it may be that something of the same kind takes place as was observed by Dupré and Page in mixtures of alcohol and water, with reference to specific heat; viz., that some mixtures have a greater specific heat than the individual constituents. In such a case, perhaps the S.R.P. might be affected by the thermic condition of the solvent, as well as by the influence of solubility.

In agreement with the supposition that greater values of (a) for the same active substance always correspond to a greater solubility in the solvent used, are the numbers given in the first table in this paper.

A. B. M.

ON THE EFFECTS PRODUCED BY ELECTRIC CURRENTS ON MERCURY IMMERSSED IN DIFFERENT SOLUTIONS.*

By M. Th. Du MONCEL.

In a former communication the author had considered the secondary current which appears at the same time as the current of polarisation to be caused by some action resulting from the combination of the two gases liberated at the electrodes. He now finds the action is more complex, consisting chiefly in amalgamation of metals in the saline solution with the mercury, under electric influence.

When mercury forms the negative electrode in an electrolyte, the force of the secondary currents depends on the oxidability of the metal added (to the mercury), the concentration of the solution, the facility of union between the metal and the mercury, and the stability of the saline combination. The continuance of the current's action is proportional to the time of electrolysis, and various circumstances affecting the union of metal with mercury. A small proportion of a salt capable of furnishing an energetic secondary current, introduced into a saline solution not thus capable, gives it the power of producing intense currents. Thus, a solution of pure sulphate of binoxide of mercury, with a negative mercury electrode, gives hardly any current; but a few particles of bicarbonate of soda or sulphate of zinc added will furnish a very strong current.

When the mercury forms the positive electrode, the energetic secondary currents produced arise most often from oxidation of the mercury, and the reduction of salts which result from it, by hydrogen condensed on the negative electrode. These currents are much more durable than those formed at the negative electrode. The most important obtained were from solutions of sulphate of soda, sulphate of zinc, sulphate of iron, and chlorhydrate of ammonia. M. Du Moncel gives a table of the results from some twenty different solutions.

PROCEEDINGS OF SOCIETIES.

ROYAL DUBLIN SOCIETY.

A COURSE of four lectures are being delivered at present by Dr. J. Emerson Reynolds upon Spectrum Analysis. These lectures are free to the public, and at the conclusion of the course a spectroscope is to be given away as a prize

* Abstract.

for the best answering. The fourth or concluding lecture takes place on Friday next, when a description of the practical applications of the spectroscope will be given. No expense has been spared as regards the illustrative experiments connected with the course, and we need hardly say that they have proved eminently successful in the hands of Dr. Reynolds.

ROYAL GEOLOGICAL AND ZOOLOGICAL SOCIETIES OF IRELAND.

THERE was a joint meeting of the above societies on Wednesday, June 11, Prof. Hull, Director of the Geological Survey of Ireland, in the chair.

Prof. MACALISTER exhibited a specimen of the *Hippopotamus Liberiensis*, and contrasted its anatomy with the extinct species.

Prof. C. R. TICHBORNE then read a paper on the "Formation of Minerals having the Spherical or Radical Form." The object of this paper was to prove that many minerals, such as wavellite, were actually separated in the colloid form as a fluid non-homogeneous with the medium from which they are deposited.

A discussion followed, in which Profs. Sullivan, Reynolds, and Hull took part.

Mr. HARDMAN's paper, "On the Occurrence of Zinc in the White Chalk of the County of Tyrone," was read in the absence of the author.

CORRESPONDENCE.

ACETAMIDE AND ETHYLATE OF SODIUM.

To the Editor of the Chemical News.

SIR,—I observe, in your report of the meeting of the Chemical Society on June 5, an account of a paper by Mr. Hartley on the above subject.

According to Mr. Hartley, acetamide, when heated with methylate of sodium, gives no methylamine, and, when heated with ethylate of sodium, it gives no ethylamine. In both instances, however, Mr. Hartley observed the evolution of ammonia; but, on making a microscopic examination of the solid product in the latter instance, he found it to consist "merely of feathery crystals of acetamide enclosed in plates of sodium ethylate." Whereupon, as appears from your report, the President thanked the author for the care and perseverance with which he had conducted his experiments.

Possibly it did not strike the President that there was any absurdity in finding that a mixture of acetamide and ethylate of sodium loses ammonia, and, having done so, consists "merely of feathery crystals of acetamide enclosed in plates of sodium ethylate."

The other objection to the results of Mr. Hartley's microscopic examination, viz., that the crystalline plates of ethylate of sodium are in reality not ethylate of sodium, but a compound of alcohol with ethylate of sodium, which suffers decomposition at the temperature at which acetamide is likely to act upon ethylate of sodium, requires some degree of knowledge of the substances in question in order to be appreciated; but, at any rate, after it has been pointed out to him, the cogency of the former of these objections can hardly fail to be palpable to the President of the Chemical Society.

That neither methylamine nor ethylamine was formed in the experiments is an interesting negative result, and will doubtless perplex chemists who regard methylate and ethylate of sodium as consisting of the alcohol radical bound to the metal by means of oxygen. The experiment of Beilstein published some twelve years ago, and showing that ethylate of sodium and acetic ether yield no trace of

common ether, and my own more recent investigations, which showed that these substances yield acetate of ethylene-sodium and alcohol, indicate that there is an equivalent of easily-replaceable hydrogen in ethylate of sodium, and negative the view that ethylate of sodium consists of ethyl and sodium bound together by oxygen.

To me the non-production of methylamine and ethylamine in the above instance appears as a natural result of the theory which I have put forward. According to me, acetamide will either refuse to attack ethylate of sodium, or else it will yield ammonia and acetate of ethylene-sodium. If Mr. Hartley perseveres in his investigation, and works in an intelligent manner, he will, I hope, find out which of these alternatives is the true one.—I am, &c.,

J. ALFRED WANKLYN.

London, June 16, 1873.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Under this heading will be found an encyclopaedic list of chemical papers published abroad during the past week, with abstracts of all susceptible of advantageous abridgment. The two half-yearly volumes of the Chemical News, with their copious indices, will, therefore, be equivalent to an English edition of the "Jahresberichte."

NOTE. All degrees of temperature are Centigrade, unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances de l'Académie des Sciences, May 26, 1873.

Estimation of the Luminous Phenomena Produced in the Interior of Transparent Media Animated by Rapid Translation where the Observer Himself Participates in the Translation.—M. Boussinesq.—The following law is enunciated by the author. The luminous phenomena perceived by an observer involved in a common movement of translation with reference to the ether, with the source of light and with interposed media, do not differ from those he would observe on contemplating the same source through the same transparent media if—there being no translation—the density of the ether became, in each respective medium, and for waves of a determinate direction, greater than it is in the proportion of unity to the square of the sum of unity and the quotient of the component of the translation velocity in the direction of the normal to the waves, by the velocity of propagation of the latter in the medium considered.

Electric Balance, and an Electro-Static Phenomenon.—M. Volpicelli.—The law of electro-static action revealed by Coulomb's balance depends on a considerable number of causes or forces as follows:—(1) Repulsion or attraction between the electric charges; (2) curvilinear induction between the two spheres; (3) rectilinear induction between them; (4) the attraction of the substances surrounding the spheres; (5) electrification of the insulating rods; (6) non-uniformity in the distribution of electricity on the spheres; (7) want of reciprocal rectilinear action of the parts of the charge distributed on the surfaces not facing each other; (8) increase of the initial charges through induction of one sphere on the other; (9) the circumstance that one may not refer entirely to the centre of one of the two spheres the electric charge which acts on the other; (10) the loss during experiment of part of the induced electricity of the first kind, and the diminution thus produced; (11) the imperfect elasticity of the suspension thread, its variability with temperature, and its hygrometric state (if not metallic). Thus it appears that the two investigations of the law, one mathematical, the other experimental, are hardly comparable. M. Volpicelli adds some remarks on an experiment described thus in

Les Mondes :—"Let the knob of a gold-leaf electroscope be touched with a bar of vulcanised caoutchouc electrified negatively by rubbing with cat-fur; then remove the rod. Next bring near to the knob a body electrified negatively; the divergence of the leaves diminishes. This phenomenon would be inexplicable if the electroscope were charged negatively; experiment shows, then, that after removal of the rod there remains an excess of positive fluid." He asks, whence this positive excess, and traces it to the fact that electrified non-conductors (unless moistened) do not communicate their electricity to metals they touch, but act merely by induction.

Researches on the Electricity Produced in Mechanical Actions.—M. Joulin.—Induced by observation of the electrical phenomena produced in belts for the transmission of motion, M. Joulin constructed new electric machines in order to study such phenomena, consisting each of a belt and two pulleys. For the pulleys he used cast-iron, copper, zinc, wood, leather, hardened caoutchouc, wool, and silk. For the belt, leather differently prepared, having a pulverulent coating of talc, resin, or oxides: or a coating of wool, silk, or gutta-percha. The maximum velocity of the belt was 1200 metres; the maximum tension weight 300 kilograms. The motor pulley rested on fixed, the other on sliding, supports. M. Joulin observed the points at which a metallic sphere (with fine needle attached) brought near the system first became luminous in the dark; and these points, taken together, gave surfaces of equal potential. He states the results for conducting and for non-conducting pulleys; and indicates how the permanent electric state is established in the machine. He finds that the free electricity perceived is the dynamical charge accompanying a current which is propagated through the belt; a charge which, according to Ohm's law, decreases from one extremity to the other of the belt, as the ordinates of a trapezium for conducting pulleys and those of two similar triangles for non-conducting pulleys.

Conditions of Maximum of Magnetic Effect in Galvanometers and Electro-Magnets.—Note by M. Raynaud.

Bulletin de la Société d'Encouragement pour l'Industrie Nationale, No. 246, June, 1873.

Notes on the Recent Progress of Chemical and Metallurgical Manufactures of England.—G. Lemoine.—The author reviews the improvements of Weldon and Deacon in the manufacture of bleaching-lime; the use of revolving furnaces in the alkali trade; the utilisation of vat-waste; the preparation of sulphate of soda by the process of Hargreaves; the method of Schloesing and Rolland for obtaining carbonate of soda by the action of chloride of sodium and bicarbonate of ammonia; the process of Gibbs for utilising burnt pyrites; the manufacture of magnesia and of carbolic acid. (We cannot help pointing out that the results of such a tour of inspection would have been more instructive if undertaken by a chemist instead of an "engineer of bridges and highways." M. Lemoine should remember the proverb, "Chacun à son métier.")

Berichte der Deutschen Chemischen Gesellschaft zu Berlin, May 12, 1873.

Sulphur Derivatives of Cymol.—A. P. Fleisch.—In the preparation of cymol by distilling camphor with the sulphide of phosphorus there are formed, in addition to cymol and other hydrocarbons of the benzol series, a body resembling phenol, soluble in alkalies, and capable of re-precipitation by acids. This substance was found to be a sulpho compound, $C_{10}H_{14}S$, or $C_{10}H_{13}SH$; a colourless liquid insoluble in water, and miscible with alcohol in all proportions. It boils at 235° to 236° , and has at 17.5° the sp. gr. 0.9975. It may be named thio-

cymol, or thiosulphhydrate. Oxidising agents convert it into cymol-bisulphite $(C_{10}H_{13})_2S_2$. By treating either this compound or the cymol-sulphhydrate with nitric acid we obtain sulphotoluylic acid—

By fusing this sulphotoluylic acid with hydrate of potassa two oxyacids are formed. The more soluble oxytoluylic acid consists of—

and is distinguished from the three acids of the same percentage composition by giving no violet colouration with the perchloride of iron. The less soluble of the two acids, when purified by repeated precipitation, gives results on analysis which agree more closely with the formula of dioxybenzoic acid, $C_7H_6O_4$, than with that of oxyterephthalic acid, $C_8H_6O_4$. The formation of the latter is, however, the more probable.

Solubility of Saline Mixtures.—F. Ruedorff.—The author remarks that on this subject little is known beyond the fact that salts are generally more or less soluble in the solutions of other salts than in pure water. He proposes to arrange for this purpose saline mixtures in two classes. I. Mixtures where no chemical change can take place, i.e., salts with identical acids or identical bases. II. Mixtures where chemical changes are possible, i.e., salts with two bases and two acids. The experiments with salts of the same base, or the same acid, showed that with some saline mixtures saturated solutions may be obtained by simply using an excess of both. In other cases the composition of the resultant solution depends on the relative proportion of the two salts submitted to the action of water. A respectively larger amount of either salt modifies the composition of the solution, so that the salts have a power of mutually excluding each other. As a matter of course, in such cases it is impossible to state the composition of the saturated solutions. Of two isomorphous salts the less soluble is expelled from solution by the more soluble.

Action of Ozone upon Pyrogallol.—J. D. Boeke.—The dark colour produced by ozone in an alcoholic solution of pyrogallol gradually disappears on prolonged action, and passes ultimately into an orange or a yellow. Beside carbonic acid and volatile fatty acids there is formed a new crystalline acid, which appears to contain 37.07 per cent of carbon, and 4.88 per cent of hydrogen, corresponding with the formula $C_6H_6O_7$.

Removal of Nitrogen from the Alkaloids.—J. D. Boeke.—The author, with reference to a preliminary communication from Prof. Hlasiwetz on the same subject, finds that when a mixture of quinine with powdered zinc sodium and excess of zinc-powder is heated in a combustion-tube to dull redness, a liquid is obtained with a pleasant smell of caraway, and free from nitrogen. The residue in the tube contained cyanide of sodium. On further experiments cinchonin was found to behave in a similar manner. Quinine may be obtained in fine crystalline needles from solution in chloroform.

Chemical Nature of Desoxybenzoins and Kindred Substances.—Br. Radziszewski.—The author considers desoxybenzoin as a keton. By submitting to destructive distillation a mixture of benzoate and phenylacetate of lime he obtained, amongst other products, benzol-benzylketon, $C_{14}H_{12}O$, agreeing both in composition and properties with desoxybenzoin. Benzoin he considers to be at once a keton and a pseudo alcohol.

Action of Bromine upon Boiling Ethyl-Benzol.—Br. Radziszewski.—The product, whether washed with water and dried, or unwashed, was entirely decomposed on distillation. Bromide of hydrogen was liberated in

abundance; the thermometer remained for a time constant at from 145° to 150° , and then rose gradually to 190° . In the retort remained a black mass containing ordinary crystalline bibromstrol. The distillate behaved in the same manner on re-distillation. Phenylbromethyl, almost pure, can be obtained by acting upon ethylbenzol at the temperature of 140° with a slight excess of bromine. On heating 2 equivalents of bromine with 1 of ethylbenzol to 145° to 150° we obtain a crystalline compound, $C_8H_5Br_2$, identical with bibromstrol, which, when passed over quick-lime at dull redness, gives two compounds—(1) A liquid hydrocarbon, C_8H_6 , boiling at 140° , and identical with Glaser's acetylnylbenzol; and (2) a crystalline substance fusing at 119° , and which when dissolved in benzol gives a fine red colour with picric acid. An alcoholic solution of picric acid gives neither a red precipitate nor colouration, which proves the absence of pyren.

Nitro-Anthracen and its Derivatives.—Ernst Schmidt.—The author seeks to identify as a new product the hydrocarbon which he has obtained, isomeric with anthracen. The similarity of the melting-point (247°) to that of para-anthracen (244°) might lead to the view that both were identical. This is not the case. Not merely the behaviour of the two bodies with reagents, but the phenomena displayed on fusion are quite distinct. Para-anthracen returns on fusion to common anthracen, its melting-point falling from 244° to 213° ; whilst the author's hydrocarbon can be fused repeatedly, and even heated to 300° , without undergoing any change of fusibility. The new hydrocarbon on treatment with boiling nitric acid is converted into a yellow nitro product, $C_{14}H_9(NO_2)$, without formation of a trace of chinon. On the other hand, para-anthracen is not nitrified by boiling with concentrated nitric acid; and common anthracen is almost entirely converted into anthrachinon and dinitro-anthrachinon. The behaviour of the new hydrocarbon with bromine differs from that of anthracen. On oxidation with chromic acid, the reaction being carefully moderated by refrigeration, a chinon is produced, $C_{14}H_8O_2$, which sublimes and crystallises in splendid red needles, fusing at 235° , and consequently totally distinct from the pale yellow ordinary anthrachinon, fusible at 273° . The new chinon dissolves in concentrated sulphuric acid with an intense and splendid indigo-blue colour. On the addition of water the colour disappears, and the chinon separates out unchanged. The mononitro product of anthracen, described by Phipson as resulting from the direct action of nitric acid upon anthracen, is not identical with the author's mononitro-anthracen, and its derivative amido-anthracen.

Propyl-Phenyl-Keton.—Ernst Schmidt and E. Fieberg.—Of the compound ketons of the aromatic series which along with phenol contain a radical of the fatty acid series, hitherto only the methyl-phenyl and ethyl-phenyl-ketons, have been examined. The authors have added a new homologue to the series by the preparation of propyl-phenyl-keton—

It is obtained by the destructive distillation of a mixture of benzoate and butyrate of lime and fractional distillation of the crude product. When purified it is a pale yellow liquid, of a pleasant aromatic odour and burning taste. It boils at 220° to 222° , and its sp. gr. at 15° = 0.99. In this keton series there appears a certain regularity in the boiling-points, similar to that observed in the normal ketons of the fatty series. Thus, methyl-phenyl-keton boils at 199° ; ethyl-phenyl-keton at 210° ; propyl-phenyl-keton at 220° to 222° . On the average the addition of CH_2 raises the boiling-point 11° .

On a Hydrocarbon in Vegetable Fats.—J. Koenig and J. Kiesow.—The former of these authors has previously stated his opinion that a hydrocarbon containing

a higher percentage of carbon must occur along with wax. This supposition they consider verified. They have obtained from hay a fatty matter, which when freed from traces of cholestérine contained—

Carbon	84.96
Hydrogen	15.28

100.24

fusing at 65° to 66° , and congealing at 65.8° to 65° .

Action of Chloretethyl upon Anhydrous Sulphuric Acid.—Th. v. Purgold.—The main product of the reaction is chlorosulphuric ether, $C_2H_5ClSO_2Cl$. When purified it distills almost entirely between 80° and 96° . The washings were found to contain isæthionie and chlorisæthionie acids. With ammonia chlorosulphuric ether reacts very violently, the mass becoming carbonised except rise of temperature is carefully prevented. With phenol the ether forms a clear liquid, which, if heated in the water-bath to 60° , gives off chloretethyl and hydrochloric acid. The products of the reaction are a thick, turbid, aromatic oil (neutral phenyl-sulphuric ether?), and two sulphacids not yet examined.

Phthaleine of Hydrochinon and Chinizarine.—F. Grimm.—The brownish-red, thick, fused mass, obtained on heating together hydrochinon and anhydrous phthalic acid, becomes gradually solid and crystalline when exhausted with boiling water. On treatment with absolute alcohol, and dilution of the extract with water, the colouring matter is first deposited. On heating the filtrate, and adding more water, the phthaleine crystallises out, and can be purified by repeated solution in a little ether, and final crystallisation from alcohol. When pure it is a white body, fusible at 232° to 234° and congealing on cooling to a yellowish vitreous mass. From hot alcohol it crystallises in white felted needles containing 1 equivalent of alcohol. If the solution is much diluted with water the crystals take the form of nacreous scales containing no alcohol, but 1 equivalent of water, which they lose at 160° to 180° . To obtain chinizarine the fused mass of phthalic acid, hydrochinon and sulphuric acid, after having been boiled in water is extracted with absolute alcohol and precipitated with water; or else treated with benzol which dissolves chinizarine readily, but phthaleine sparingly. When purified by re-crystallisation from alcohol and ether it is composed of $C_{14}H_8O_4$. It crystallises from ether in orange scales; from benzol and alcohol in dark red needles. The solutions in ether and in sulphuric acid display a greenish-yellow fluorescence resembling that of Stenhouse's munjistin, prepared from munjeet. This body possibly stands in the same relation to chinizarine as does purpurine to alizarine. When heated chinizarine sublimes in coloured needles and plumose crystals resembling alizarine, leaving a shining charcoal behind. The melting-point of the sublimed body is 194° to 195° ; that of the crystals from alcohol 192° to 193° . With alkalis it yields blue solutions with a slightly violet tinge, which is most decided in case ammonia is employed. With baryta it gives a fine blue-violet compound; with alumina a red lake playing into violet; and with magnesia a deep blue-violet body. Chloride of iron gives a brown-red, and acetate of lead a dull red precipitate in the feebly alkaline solution. If the alcoholic solution is allowed to stand for some time it becomes colourless; whilst a deep violet or black precipitate is deposited, which re-dissolves in alkalis with a blue colour. At a boiling heat the alkaline solution is decolourised by zinc-powder, but on exposure to air quickly resumes its colour. Chinizarine is not only isomeric with alizarine, but the two bodies stand in the closest connection. If the vapours of chinizarine are passed over heated zinc-powder we obtain white shining scales which, after sublimation, melt at 210° to 218° , and give a red compound with picric acid. It is highly probable that chinizarine is converted into anthracen

when heated with zinc-powder. The author considers that his results support the view of Fittig that anthraquinon is a double keton of benzol. The following observations on the absorption spectra of chinizarine and alizarine, due to Prof. Kundt, may be of interest. It should be noted that the alizarine had merely been purified by sublimation, and might, therefore, contain purpurine:—

ALIZARINE.
D at 172° of the scale; C at 157.5°.

CHINIZARINE.
B, 191°; F, 208.5°; G, 243°.

1. *Solution in Soda Lye.*

Three dark bands; their centres.

- (1). 166.
- (2). 177.
- (3). 190 (very faint).

Only a direct band visible, their centres.

- (1). 169.
- (2). 121.

2. *Solution in Carbonate of Potassa.*

(1). Dark band above mentioned at 166. (2) and (3) forming a broad washed-out band in which the two maxima of darkness were not easily distinguished.

In a concentrated solution only one band, absorbing the whole blue portion from 167°.

In dilute solutions 2 faint dark bands.

- (1). 171.
- (2). 184.

Solution in Ether.

If concentrated no bands visible; the whole blue part absorbed from 190°.

If less concentrated a faint dark band at 193°

Another band beginning at 205°; behind this a maximum of light, followed again by absorption.

Three bands visible.

- (1). 195°
- (2). 201°
- (3). 209.

Fainter and twice as broad as the former.

Solution in Sulphuric Acid.

In concentrated solutions a very peculiar faint band at 163°.

Appearance of a band at 181°.

Dilute solutions; a very faint band at 203°.

In concentrated solutions three bands; in dilute only two.

- (1). At 183°.
- (2). At 197°.
- (3). Very faint at 212°.

Mono-Bromacrylic Acid Obtained from β -Bromopropionic Acid.—R. Wagner and B. Tollens.—The authors obtained the acid $C_3H_3BrO_2$ by treating β -bromopropionic acid with potassa. It is capable of combining with hydrobromic acid to form a crystalline acid fusible at 63° to 64°, and identical with the bibromo-propionic acid.

α -Bromo-Propionic Acid Obtained from Propionic Acid.—G. Phillippi and B. Tollens.—The two bromo-propionic acids differ in crystalline form. A solution of each is induced to crystallise by the addition of a solid particle of its own kind; whilst a portion of the other not only fails to set up crystallisation, but is itself dissolved. The two acids are still more clearly distinguished by their behaviour with nascent hydrogen; the β modification yielding acrylic acid, whilst the α form produces propionic. The respective salts of the two acids are also distinct.

Nature of the Elements.—J. A. Groshans.—(Two papers.) Reserved for complete insertion.

Thermo-Chemical Determination of the Affinity of Oxygen for Sulphur, Selenium, and Tellurium.—Julius Thomsen.—The author concludes that the mutual affinity of oxygen and selenium in both stages of oxidation is smaller than that of oxygen and sulphur, and also than that of oxygen and tellurium, which latter element holds a middle place in the scale. This result may seem unexpected, as it is commonly supposed that the relations

of affinity in a group of elements increase or decrease with the atomic weight. Such a proportion occurs in the case of hydrogen compounds when the affinities decrease as the atomic weights increase, as—

In oxygen compounds this law does not hold good, the affinities of the same group for oxygen being—

Chem. Notices 5

The same holds good with the group just examined, the affinities for oxygen being—

In both these elementary groups the two first members have the greatest resemblance, in a chemical point of view, and differ more widely from the third.

Notes from the Greifswald Laboratory.—H. Limpricht.—(1). The picrate and dibromide of phenanthren have been formed and examined by Hayduk. The former, $C_{14}H_{10}C_6H_3(NO_2)_3OH$, forms fine yellow acicular crystals, fusible at 143°. The dibromide, $C_{14}H_{10}Br_2$, forms four-sided prisms which fuse at 98°, and undergo spontaneous decomposition even in closed vessels. Bromphenanthren, $C_{14}H_9Br$, one of the products of the decomposition of the above salt by heat forms slender white prisms, fusible at 63°. The chinon of phenanthren, $C_{14}H_8O_2$, constitutes orange needles, fusing at 202°. (2). Paulz, in submitting chlorinated sulphide of toluol, $(C_6H_4Cl.CH_2)_2S$, to distillation obtained a compound, $C_{12}H_8S_2$, in white brilliant scales, fusible at 208°, and capable of sublimation without decomposition. (3). Pechmann has succeeded in obtaining the chloride of benzylsulphonic acid, $C_6H_5CH_2SO_2Cl$.

On Isokreatine.—H. Salkowski.—This compound is an isomer of kreatine, obtained by the addition of alanine and cyanamide. It is distinguished from kreatine by taking up no water of re-crystallisation. The aqueous solution, if free from alanine, remains colourless when boiled with oxide of copper.

Ketons Formed from Aromatic Acids and Hydrocarbons.—M. Kollarits and V. Merz.—Reserved for full insertion.

Bulletin de la Societe Chimique de Paris, tome xix., No. 11, June 5, 1873.

Preparation and Properties of Oxymaleic Acid.—Ed. Bourgoin.—We have elsewhere given the substance of this paper.

Claim of Priority raised by J. Thomsen respecting the Principles of Thermo-Chemistry.—M. Berthelot.—A controversial paper.

Action of Hydrochloric Gas upon the Compound Ammonias.—Ch. Lauth.—It is known that "Paris violet" is prepared on the large scale by the action of oxidising agents upon methyl- and dimethyl-aniline, and that these bases are obtained by heating the hydrochlorate of aniline with methylic alcohol under pressure. In the "Neues Handwörterbuch der Chemie," p. 632, Hofmann states that methyl-aniline, thus prepared, contains always methyl-toluidine, and concludes that the formation of the violet is analogous to that of magenta, with the difference that in the former case we operate upon methylated bases. This view does not agree with the following facts:—Methyl-aniline yields, on oxidation, larger quantities of violet the higher is its degree of purity. It seems that, if it were proper to operate upon a mixture of methyl-aniline and methyl-toluidine, it would be simpler to set out with a mixture of aniline and toluidine, instead of a pure aniline. Again, the methyl-aniline, obtained by the action of iodide of methyl upon aniline, yields violet, though the reaction takes place at a very low temperature, whilst the introduction of methyl into the residue C_6H_5 only takes place, according to Hofmann, at an elevated temperature. The presence of methyl-toluidine cannot be

shown in methyl-aniline, either by fractional distillation or by the fractional crystallisation of salts. A current of dry hydrochloric acid gas was passed into methyl-aniline kept in a state of gentle ebullition, the apparatus being disposed so as to absorb the excess of gas on its exit from the receiver, and to collect the gases formed during the reaction. The presence of the chloride of methyl could not be mistaken. On operating upon 50 grms. of methyl-aniline, more than 30 litres of gas are collected in two or three hours; the disengagement then slackens, but does not entirely cease for two days. When the liberation of chloride of methyl is at an end, the apparatus is cooled. The product becomes a hard crystalline mass, which is dissolved in boiling water and crystallised. The crystals, on treatment with caustic soda, yield pure aniline. This aniline, reproduced from methyl-aniline, does not contain toluidine. In a similar manner, methyl-toluidine, heated in a current of hydrochloric gas, yields chloride of methyl and toluidine, without a trace of aniline. These facts prove that the methyl-aniline employed in the manufacture of Paris violet contains neither toluidine nor methyl-toluidine, and that, contrary to the view of Hofmann, the production of this colour does not require the simultaneous action of methyl-aniline and of methyl-toluidine. The action of hydrochloric acid upon these bases appears to be of general applicability, as it will permit us to recognise the presence of alcoholic groups of the fatty series, simple or substituted, and thus determining the nature of some isomeric bodies.

Method of Analysing Glycerines.—P. Champion and H. Pellet.—Commercial glycerines, according to the manner of their preparation, contain certain foreign bodies, such as glyceric ethers, volatile fatty acids, &c. Samples agreeing in specific gravity and in whiteness may differ in their degree of purity. The following process will be found useful for ascertaining their quality:—An acid mixture is prepared beforehand, consisting of 1 part of fuming nitric acid and 2 parts of pure sulphuric acid at 66° Baumé. The nitric acid should be previously deprived of its hyponitric fumes, by heating it in the water-bath to 80°, and passing through it a rapid current of air until all the colour has disappeared. 250 grms. of the refrigerated mixture are then weighed out, and placed in a suitable flask surrounded with cold water. On the other hand, 30 grms. of the sample of glycerine are weighed out. The glycerine is poured, drop by drop, into the nitrosulphuric mixture, constantly stirring with a thermometer, and taking care that the mixture does not exceed the temperature of 25°. The exact quantity of glycerine employed is then determined by a second weighing of the beaker. After standing for half an hour, the nitroglycerine collects at the upper part of the acid mixture, and the whole is poured into a large earthen vessel containing from 1 to 2 litres of cold water, avoiding too great a development of heat. The nitroglycerine is precipitated in states which vary with the purity of the glycerine operated upon. If a crude, impure sample, has been employed, the product is opaque, and collects with difficulty. In certain cases, it takes the form of clots, which do not unite on shaking. This comes from the interposition of a quantity of water, which forms an emulsion with the nitroglycerine. In order to dry the product, it is saturated with a weak solution of caustic soda. It is washed, and, when the excess of water has been removed, it is mixed with an equal volume of wood-spirit. It is evaporated in the water-bath, and weighed. The water is carried off along with the wood-spirit, and a clear product is obtained, more or less coloured according to the purity of the glycerine. Two successive weighings are necessary to ascertain the total expulsion of the wood-spirit and the water. The preliminary washing of the nitroglycerine is best performed in a tall glass jar, by passing a constant current of water down to the bottom by means of a glass tube. The washing may require from one to two hours. Lime, if present, should be directly determined in a portion of 30 grms. Chemically pure glycerine,

concentrated *in vacuo* at 120° to 150°, yields 190 per cent of nitroglycerine. The operator is liable to violent headaches from the odour of the nitroglycerine, which may be treated with ammonia and acetate of morphia.

Determination of Nitroglycerine in Different Species of Dynamite.—P. Champion and H. Pellet.—Dynamites may be divided into two classes, according to the nature of the absorbent:—(1). Those with an inert base, such as silica, Boghead ashes, Tripoli, &c. (2). Those which, like dualine and lithofraqueur, contain resin, finely-powdered coal, nitrate of potash or soda, or other bodies which are decomposed on explosion. In examining the former kind, 25 grms. of dynamite are weighed out and exhausted with pure hot methylic alcohol. The solution is then evaporated in the water-bath till the weight becomes constant. Dynamites with an active base are treated with boiling water, which dissolves out nitrates and separates resins, which rise to the surface. The nitroglycerine is then separated from the insoluble residue by means of wood-spirit, as above.

Contributions to the History of Glucinum.—A. Atterberg.—An account of the composition of some of the salts of this metal.

Polytechnisches Journal von Dr. E. M. Dingler, first number for May, 1873.

Account of a Visit to the Nitroglycerine Works of G. M. Mowbray, situated near North Adams, Massachusetts, U.S.—A. Ott.—This lengthy paper contains a detailed account of the method of preparing, on the large scale, nitroglycerine, which is here made with great care, and is, after having been purified, frozen either in bulk or in cartridges. The substance thus made differs in some particulars from Nobel's nitroglycerine; the former freezes at 7.2°, and contracts thereby 1-12th in bulk; the latter freezes at 12.8°, and expands thereby considerably. The American product cannot explode as long as it remains frozen, and is quite as colourless as water. The nitric acid employed in the preparation is manufactured on the premises, and carefully freed from any hyponitric acid, which, according to Mowbray, is an important point in the process. The glycerine is also taken quite pure, and the nitration is conducted very slowly, and aided by keeping the vessels very cold, and, moreover, by minutely dividing the liquid by means of blowing air through it. The crude nitroglycerine is carefully purified, and afterwards frozen.

Estimation of the Oxygen present in the Gases Escaping from the Lead Sulphuric Acid Chambers.—F. Bode.—This paper contains a series of calculations exhibiting a method of arriving at an approximate result, sufficiently accurate for all practical purposes, as regards the quantity of oxygen present in the gaseous mixture alluded to.

New Industrial Process of Stearine Manufacture.—Professor Bock.—The author points out that the so-called acid saponification is misunderstood, that in reality no saponification takes place at first, and that the preliminary action of the sulphuric acid, when the operation is properly conducted, is to dissolve and disintegrate the albuminous and cellular tissues present in the raw fat, and next to dissociate the neutral fats, whereby the fatty acids may be obtained in a state of great purity.

Testing of Sulphate of Alumina (Patent Alum) for Sulphuric Acid.—J. Reimann.—The pulverised salt is put into alcohol, wherein it is insoluble, while any free sulphuric acid it might contain is soluble therein, and may be estimated by titration after filtration of the alcohol. Pure sulphate of alumina yields, with a logwood decoction, a deep violet colour, but, if free sulphuric acid is present, the colour becomes brown.

Composition of a Pottery Glaze.—Dr. H. Seger.—In 100 parts, the glaze was found to consist of—Silica, 40.56;

alumina, 6.07; oxide of lead, 40.04; peroxide of iron, 2.59; protoxide of manganese, 7.14; lime, 2.58; alkalis, 1.02. This glaze may industrially be obtained by mixing the following ingredients:—Quartz, 28 parts; litharge, 40; pipe-clay, 18; peroxide of manganese, 9; chalk, 5. The substances, finely ground, should be ignited, and next again ground to an impalpable powder, previous to being applied to the potteryware (hard earthenware).

Journal für Praktische Chemie, No. 1, 1873.

Chemical Constitution of some of the Uranium Metals.—Dr. C. Winkler.—This exhaustive essay treats at length on the composition and chemical constitution of some minerals recently found in Saxony, viz.:—Uranospherite, consisting, in 100 parts, of—Oxide of uranium, 43.79; oxide of bismuth, 38.39; water, 4.84; oxide of cobalt, 4.22; oxide of iron, 2.75; carbonate of lime, 1.15; arsenious acid, 1.82; quartz (silica), 1.05. Formula—

Walpurgin, in 100 parts—Oxide of bismuth, 61.43; oxide of uranium, 20.29; arsenious acid, 11.88; water, 4.32. Typical formula—

Trögerit, in 100 parts—Oxide of uranium, 59.73; arsenious acid, 17.39; water, 17.03; oxide of bismuth, 0.74; oxide of copper, 0.56; oxide of cobalt, a trace; gangue, 1.69. Typical formula—

Zeunerit, in 100 parts—Oxide of copper, 7.49; oxide of uranium, 55.86; arsenious acid, 20.94; water, 15.68. Formula—

Uranospinit, in 100 parts—Lime, 5.47; oxide of uranium, 59.18; arsenious acid, 19.37; water, 16.0. Formula—

Contribution to our Knowledge on Indium.—C. Roessler.—The author prepared an ammonium-indium alum which, on being analysed, was found to contain, in 100 parts—Oxide of indium, 25.47; ammonium, 4.82; sulphuric acid, 26.66; water, 40.04. Formula—

This alum is very soluble in water, but insoluble in alcohol; the acid solution becomes turbid by boiling.

Analysis of the Chalybeate Water of Homburg.—Dr. R. Fresenius.—The source yields 2160 litres of water in twenty-four hours. Sp. gr. of the water at 20°, 1.007080; temperature of the water (that of the air being, at the moment of observation, 11°), 18.75°. 1000 parts of this water contain (the carbonates taken as neutral salts)—Chloride of sodium, 5.863199; chloride of potassium, 0.248320; chlorolithium, 0.012067; chlorammonium, 0.013187; chlorcalcium, 0.497721; chlormagnesium, 0.315457; iodmagnesium, 0.000015; brommagnesium, 0.000676; nitrate of potassa, 0.001874; sulphate of lime, 0.003725; sulphate of strontia, 0.010616; sulphate of baryta, 0.000420; carbonate of lime, 0.722479; carbonate of magnesia, 0.061417; carbonate of protoxide of iron, 0.071385; carbonate of protoxide of manganese, 0.004054; carbonates of the protoxides of cobalt and nickel, 0.000024; basic phosphate of lime, 0.001017; silica, 0.017190; total of fixed constituents, 7.844843; carbonic acid combined with the carbonates, 0.378699; free carbonic acid, 2.042990; sulphuretted hydrogen, 0.000671. The following substances are present in this water in unweighable quantity:—Oxide of caesium, oxide of rubidium, alumina, oxide of copper, oxide of antimony, arsenic acid, boracic acid, fluorine, organic matter, nitro-

gen, and marsh gas. 1000 c.c. of water contain 1082.93 c.c. of free, and 200.74 c.c. of combined, carbonic acid, and 0.4583 c.c. of sulphuretted hydrogen.

What is to be considered Good Potable Water?—E. Reichardt.—An hygienico-chemical essay.

Metamorphosis of Bones.—Dr. C. Aeby.—A pathologico-chemical memoir.

No. 2, 1873.

Estimation of Nitric Acid Present in Potable Waters by Means of Indigo.—F. Fischer.—This paper contains, in the first place, a *résumé* of the researches of Marx, Goppelsroeder, Bemmelen, and others, on this subject; and further, the results—chiefly exhibited in tabulated forms—of the author's experiments made with the view to ascertain the correctness of this process: it would appear that, with due care and frequent repetition of the estimation of nitric acid in the same sample of water, reliable results may be obtained.

Artificial Formation of Fluoride of Calcium and of Heavy Spar.—Th. Scheerer and E. Drechsel.

A Very Simple and Rapidly-Acting Method of Filtration, based upon Bunsen's Process.—Dr. E. Fleischer.—This paper is illustrated with woodcuts.

On some of the Derivatives of the Cyan-Carbonic Acid Ether.—A. Weddige.—When the ether is treated with alcoholic ammonia there is formed cyan-ammonium-urethan according to the formula—

concentrated hydrochloric acid converts the cyan-carbonic acid ether, even in the cold, into oxalic acid and chloride of ammonium. When the free ether or its alcoholic solution is treated with sulphuretted hydrogen there is formed a crystalline, lemon-yellow-coloured substance, soluble in boiling water; fusion-point 63° to 64°. The formation of this body is elucidated by the following formula:—

By treating the cyan-carbonic-acid ether with sodium amalgam there is not formed a combination corresponding to kyanäthin.

Chemical Constitution of the Benzol Compounds.—Th. Petersen.—This monograph does not admit of abstraction.

No. 3.

Action of Potassium Sulphydrate upon the Aromatic Nitriles.—A. Weddige.—Pure cyan-benzyl, $\text{C}_6\text{H}_5\text{OH}_2\text{CN}$, was treated with an excess of an alcoholic solution of potassium sulphydrate, with the view of obtaining the potassa salt of the dithio-alpha-toluylic acid, $\text{C}_6\text{H}_5\text{CH}_2\text{CS}_2\text{SK}$; but instead of this, the result of the reaction was the formation of a body free from sulphur, and corresponding in composition to the alpha-toluylic acid amide, $\text{C}_6\text{H}_5\text{CH}_2\text{CONH}_2$: this substance is difficultly soluble in cold—more readily soluble in hot—water, readily soluble in alcohol, but very difficultly in ether; fusion-point, 154° to 155°; boiling-point, 181° to 184°.

Action of some Chlorides upon Sodium Alcoholate.—A. Geuther and F. Brockhoff.—This exhaustive monograph is divided into the following sections:—Pentachloride of phosphorus and sodium alcoholate; perchloride of ethylen and sodium alcoholate; perchloräthan and sodium alcoholate; trichlor-ethylen-chloride and sodium alcoholate; dichloräthylen-chloride and sodium alcoholate; monochloräthylen-chloride and sodium alcoholate; perchlormethan and sodium alcoholate.

Chemical Constitution of the Elementary Molecules.—Dr. H. Kolbe.

Observations on the Maxite and Leadhillite found in Sardinia.—H. Laspeyres.—This paper contains critical remarks on Bertrand's paper on this subject, published in the first number of the *Bulletin de la Société Chimique de Paris* for this year.

Bulletin de l'Académie Impériale des Sciences de St. Petersburg, Vol. xviii., No. 3, February, 1873.
Contains no chemical papers.

Revue Scientifique de la France et de l'Etranger, No. 48, May 31, 1873, and No. 49, June 7, 1873.
These two numbers contain no chemical papers.

Revue Hebdomadaire de Chimie Scientifique et Industrielle, par Ch. Mène, No. 22, April 4, 1873.
This number again contains not a single chemical paper.

Les Mondes, Revue Hebdomadaire des Sciences, par L'Abbé Moigno, Tome xxxi., No. 7, June 12, 1873.
This number contains no original chemical matter.

MISCELLANEOUS.

Determination and Characteristics of Citric Acid.—Soluble citrates mixed with acetate of baryta, either hot or cold, produce a white amorphous precipitate, being citrate of barium with 14 aq. If, after precipitation, an excess of acetate of baryta be added, and the mixture heated in a water-bath, the precipitate becomes heavy and granular; it loses one-half of its water of crystallisation, and has now 7 aq. The presence of other organic acids does not interfere; the granular salt is absolutely insoluble in water, and citric acid may thus be easily determined. If the solutions are very dilute, they must be concentrated by evaporation, after additions of acetate of baryta, or the precipitate will consist of crystalline needles containing only 5 aq. Mr. J. Creuse, commenting upon M. Kammerer's paper, claims priority on the subject. He also states that M. Kammerer is in error in describing citrate of barium as insoluble in water. He contends that the citrate of baryta should be converted into sulphate before weighing, as it is very hygroscopic.

NOTES AND QUERIES.

Red-Coloured Magenta.—I have a sample of a colouring matter which appears like ordinary magenta, in a greenish golden cake soluble in water; but it dyes a brownish red tint, not at all like the salts of rosaniline. With hydrate of soda it gives a reddish precipitate or yellow if the alkali be in large excess, and a deep yellow solution. Can any of your readers inform me what this yellow solution contains, and how to utilise it? I believe the stuff is made from some residuum.—C. H.

New Ozone Generator.—Messrs. Tisley and Spiller send word that Mr. Wills stated, on commencing the reading of his paper at the meeting of the Chemical Society on the 5th of June (*CHEMICAL NEWS*, vol. xxvii., p. 292), that the generator was not his own contriving, but was manufactured by Messrs. Tisley and Spiller, and he thought it such an advance on all previous instruments as to deserve a proper notice of the Chemical Society.

Ilmenium.—Miller says that Hermann supposed he had discovered a new metal, but had since proved it to be a mixture of tantalum and columbic anhydrides. Dana ignores it, as do all the authorities I have access to. So I was not a little surprised to see the notice in the *CHEMICAL NEWS*, vol. xxvii., p. 59, of Hermann's monograph, giving atomic weight, oxides, and other particulars of ilmenium, when he was represented as admitting his former ideas to be erroneous. Is Hermann the only authority for ilmenium, and are his views admitted by many chemists to be correct? If so, why has it not a place in modern chemistries?—PETER JACOBUS.

Manipulation of Spongy Platinum.—In view of the fragility of the ordinary preparations of spongy platinum, as used for kindling gases, Professor Phin recommends the following capital plan:—"We have succeeded admirably with pumice-stone, which we first form into a cylinder of the proper size—say, 3-8ths of an inch in diameter—

and then cut into discs about the 20th of an inch thick, by means of a fine saw. These discs are soaked for some time in a strong solution of bichloride of platinum in alcohol, and afterwards for an equal period in an alcoholic solution of sal-ammoniac. After being ignited, these discs inflame a jet of hydrogen readily, and we find that they retain their power quite as well as the more delicate forms in common use." *Handicraft*.

"Experiments with the Torsion-Rod for Determining the Mean Density of the Earth," forming vol. xiv. of the *Memoirs of the Royal Astronomical Society*. By Francis Baily, Esq., Vice-President of the Society. London. 1843.

P. 81.—"I shall now proceed to take a review of the different series, for the purpose of pointing out such of them as may appear to be less deserving of confidence than the rest, on account of certain discordances which seem to impair their accuracy. I have already noticed that slight differences occasionally arise in the mean results. . . . But it is not to cases of this kind that I am now about to allude. . . .

The case, however, is somewhat different with those experiments which, during any given series or course of operations, do not exhibit so regular and uniform a system; but, on the contrary, show evident signs of some disturbing force that has hitherto escaped detection, affecting not only the march and direction of the resting point, but also the time of vibration, thus impairing the accuracy, or at least the uniformity, of the results. The most remarkable instance of this kind occurs in the 33rd series . . . ; and it is worthy of notice that in this series there are no less than three experiments, where the arc of vibration increased instead of being diminished: an evidence of some extra-disturbing force, which has baffled every effort of mine to unravel. Indeed one of the results, where this last-mentioned experiment is involved in the computation, makes the density "of the earth" as high as 5.150; but this rapid and enormous increase is partly assisted by a sudden change in the march of the resting point about that time, so that a variety of circumstances have here combined to produce this extraordinary result. And, astounding as this great quantity may appear, it should be noticed that one of the single results on the same day is as low as 4.292; so that by this counteraction the daily result is not so very materially affected. I am unable to throw any light on the cause of these and other discrepancies which occurred in this particular series. A similar instance, although not quite so discordant in magnitude, occurs in the 35th series. . . . We have here also one of the experiments exhibiting an increase in the arc of vibration, and thus impairing the result in which its computation is involved. The last result likewise, in this series, is of very considerable magnitude, being as high as 7.425; but here also we have a single result on the same day as low as 4.713; so that, astounding as this quantity also may appear, yet by this counteraction the daily result is not sensibly affected."

P. 83.—"Other series might be adduced where the discordances between the single and daily results, although not so great as those already mentioned, evidently show that some disturbing force was in operation, which either escaped detection at the time, or against the influence of which it was found impracticable wholly to protect the apparatus. These cases have occurred mostly with the light balls, and when the torsion force . . . has been weak; and their effect has been exhibited by some irregularity in the march of the resting point, or in the time of vibration."

P. 83.—"But, even when discordances of considerable magnitude, of the kind above mentioned, do not occur, we yet find that the mean result of two several days (the mode of operation continuing the same in both cases) sometimes differ from each other by a greater quantity than might have been previously imagined . . . which renders it manifest that we cannot always expect rigorous accuracy and uniformity in such delicate investigations, under all the various conflicting circumstances that occur in carrying on the operations."

MEETINGS FOR THE WEEK.

MONDAY, 23rd.—Royal Geographical, 8.30.
WEDNESDAY, 25th.—Society of Arts, 4. Anniversary.
Geological, 8.
THURSDAY, 26th.—Royal Society Club, 6.30. Anniversary.
FRIDAY, 27th.—Quekett Microscopical Club, 8.

TO CORRESPONDENTS.

* Vol. XXVI. of the *CHEMICAL NEWS*, containing a copious index, is now ready, price 12s. 4d., by post, 12s., handsomely bound in cloth, gold lettered. The cases for binding may be obtained at our office, price 1s. 6d. Subscribers may have their copies bound for 2s. 6d. if sent to our office, or, if accompanied by a cloth case, for 2s. Subscribers wishing to complete their sets of volumes are requested to apply to the publisher, who will give them information respecting scarce numbers and volumes. Vol. xxvii. commenced on Jan. 3rd, and will be complete in twenty-six numbers. **READING CASES**, price 1s. 6d. each, post free, may also be obtained at the Office.

ERRATA.—Vol. xxvii., p. 262, for $C + \frac{b}{a}$ read $\frac{b}{a} \times C$.

R.—"High Farming without Manure," by G. Ville. This author has also published several valuable works in French on agricultural chemistry.

A Subscriber.—Consult Dr. Hassall's book on the subject.

SUPPLEMENT TO THE CHEMICAL NEWS.

Vol. XXVII. No. 708.

ON THE DETERMINATION OF PHOSPHORIC ACID IN ALL PRODUCTS OF AGRICULTURAL AND PHYSIOLOGICAL IMPORTANCE.

By M. JOULIE.

(Continued from p. 230).

PART II.

THE author proceeds to give an account of the application of his "citro-uranic method" to a variety of cases.

Insoluble Phosphates (consisting chiefly of phosphate of lime, accompanied by carbonate of lime, silica, oxides of iron, alumina, fluoride, chloride, and iodide of calcium, and peroxide of manganese).—Whatever may be the composition of the mineral, the analysis consists of the following operations:—Sampling, solution, precipitation of the phosphoric acid in the state of ammoniacomagnesian phosphate, and volumetric determination of the phosphoric acid contained in the precipitate.

1. **Sampling.**—This operation, simple as it seems, requires particular attention if comparable results are aimed at. If the phosphates are ground and in bags, a scoop is plunged into about twenty of them taken at random, and the contents are emptied upon a large sheet of paper. The whole heap is then thoroughly stirred and mixed together, and two or three 8-oz. bottles are filled with the powder. This operation should be performed in presence of the seller and the buyer, or their representatives, who both put their seals on the bottles, and sign, if needful, an account of the taking of the sample. One of the bottles is sent to the laboratory where the analysis is to be conducted; the others are reserved for verifications, if needful. The chemist who receives the sample registers the date of arrival, the professed nature of the sample, and the marks on the seals. The contents are then sifted upon a large sheet of paper; if any particles do not pass the sieve, they are powdered till the whole passes through. The mass is then mixed with a spatula, and then re-passed through a coarser sieve, and returned to the bottle. If the phosphates are unground (in the rock) the difficulties are greater. To obtain a product which shall fairly represent the average composition of the whole, about a hundred spadefuls are taken from different parts of the mass, and ground up in the crushing-mill. The powder is then carefully mixed and stirred together, and the bottles filled as above.

2. **Solution.**—(a). The simplest method is to weigh out 5 grms. of the sample, previously finely powdered, and introduce it into a flask marked at 100 c.c. It is first moistened with a little water, and 20 c.c. of nitric acid are then added. If the substance effervesces, the acid is only added by degrees, lest the liquid should boil over. When the effervescence has subsided, the flask is placed on a sand-bath, and heated for half an hour to a temperature close upon ebullition, and agitated from time to time. The flask is then cooled, by plunging it into cold water. When it is brought to the ordinary temperature, it is filled up to the 100 c.c. mark, and shaken, after having been closed with an india-rubber stopper. The contents of the flask are then thrown upon a filter, and the filtrate received in a wide-mouthed bottle provided with a ground stopper.

During filtration it is well to cover the bottle and the funnel with a bell-glass to prevent loss by evaporation. This procedure requires little time, and is followed at present in many laboratories. It is very suitable in all cases where the phosphate is entirely soluble in dilute nitric acid. In such a case no error is committed by taking one-fourth or one-half of the solution, and supposing it to represent the same fraction of the weight of material originally taken; but, if the sample contains a certain quantity of insoluble matter, an error is committed proportional in importance to the quantity of insoluble residue.

(b). Wherever insoluble matter is present, the following method is preferable:—5 grms. of the sample are weighed out, and introduced into a flat-bottomed beaker; 20 c.c. of water are then introduced, and the whole shaken to moisten the powder. The beaker being then covered with a watch-glass, 20 c.c. of nitric acid are added with a pipette, the watch-glass being raised on one side with the point. If the effervescence is brisk, the acid is only introduced by degrees. When all the acid is introduced, and the effervescence has nearly subsided, the beaker is set upon the sand-bath, and kept for half an hour close upon ebullition, stirring from time to time. The watch-glass is then taken off the beaker, its under-surface washed with a stream of distilled water from the washing-bottle, the liquid stirred and allowed to settle. It separates into a sediment and a clear supernatant liquid. The clear portion is decanted into a flask containing 100 c.c.; boiling water is poured upon the residue. It is again allowed to settle, and the clear portion is again decanted into the flask, and so on till the liquid is no longer acid. This result is obtained before the flask is full. The liquid is then cooled, if necessary, and filtered. If two chemists operate upon the same sample, and the one prepares his solution by the method *a*, and the other by ordinary filtration, a difference of 4 to 5 per cent may easily arise from this cause. By using the process *b*, these sources of error cease.

3. **Precipitation.**—To precipitate phosphoric acid, we take generally 5 c.c. of the liquid. If the sample has left a large amount of insoluble matter, it may be supposed poor in phosphate, and in this case 10 or even 20 c.c. may be taken. This is run into a beaker, with the addition of 10 c.c. of the citro-magnesian liquid (this liquid should contain 400, and not 500, c.c. of ammonia at 22° B.) and a large excess of ammonia. The mixture is gently stirred with a glass rod. No immediate turbidity ought to appear; should this be the case, it is a proof that the quantity of citro-magnesian liquid is insufficient, and 10 c.c. more are at once added. It is stirred again when the precipitate of the double phosphate begins to appear. To ensure complete precipitation, the liquid should stand four or five hours, and preferably overnight. The deposit forms more quickly the less heat the liquids evolve on mixture, and the greater the excess of ammonia. As heating results from the combination of ammonia with the acids of the solution, it may be readily avoided by nearly neutralising the solution of phosphate with dilute ammonia before adding the citro-magnesian liquid, and in adding a large excess of ammonia.

4. **Volumetric Determination of the Phosphoric Acid.**—The precipitation being complete, the liquid is filtered, the precipitate is washed with water containing 10 per cent of ammonia, re-dissolved in nitric acid of the same dilution, neutralised with ammonia, mixed with 5 c.c. of the solution of acetate of soda, and titrated with the uranium solution as already directed. The amount of moisture should always be determined, and expressed in the report of the analysis along with the phosphate.

Bone Products and Manures.—In bones and their modifications—such as boiled bones, bone-ash, animal charcoals whether fresh or exhausted, precipitated phosphates, &c.—as well as in manures, natural or artificial, the determination of phosphoric acid is effected exactly as in natural phosphates. In some cases, water and organic

matter create special difficulties, and require particular manipulations.

Animal charcoal is often so damp, and so far from homogeneous, that no certain result could be obtained with a sample of 5 grms.; in such a case, 400 to 500 grms. must be taken, and the moisture in it must be determined by drying in the water-bath. The residue is then powdered, mixed, and sifted, and 5 grms. weighed out for the determination of the phosphoric acid.

Bones and many manures contain organic matter in greater or less quantity. These substances, besides shielding the phosphates from the solvent action of the nitric acid, render the solution so glutinous that the filtrations are rendered very tedious. For this purpose, 10 to 20 grms. are placed in a platinum capsule, and calcined at very low redness. Manures containing soluble phosphoric acid should never be ignited, as a part of the acid phosphate of lime may be reduced by the action of the carbon, and thus some of the phosphorus may be volatilised. If it is necessary to incinerate such manures, they should be previously mixed with their own weight of pure lime. The loss of weight during calcination must be carefully noted. The ash is then powdered, mixed, and 5 grms. are weighed out for the determination of the phosphate.

Determination of Phosphoric Acid in the Ash of Plants, in Soils, Dung, &c.

(a). *Ash of Plants.*—Phosphoric acid can be determined in the ash of plants by proceeding exactly as with natural phosphates, the precaution being taken to separate the silica. 2½ grms. of the ash are weighed out, placed in a porcelain capsule, moistened with a little water, and then treated with 10 c.c. of pure nitric acid, keeping the capsule covered with a watch-glass. When the effervescence has ceased, the capsule is set on the sand-bath, and kept covered. When the liquid begins to boil, it is uncovered, the bottom of the watch-glass is washed into the capsule by means of the washing-bottle, and the liquid evaporated to dryness. The residue is heated for half an hour, let cool, moistened with a little nitric acid, to which water is added after an hour; it is then boiled gently, and filtered, or decanted into a bottle marked at 50 c.c.

(b). *Soils.*—The sample, having been properly taken, is treated exactly as has been directed for the ash of plants, aqua regia being used instead of nitric acid. When the silica has been separated out and washed, the filtrate and washings are mixed, and evaporated down to about 35 c.c. We add now 10 c.c. of citro-magnesian liquid, and a great excess of ammonia. The mixture is now gently stirred; if an immediate turbidity appears, more citro-magnesian liquid is added to re-dissolve it, and the whole, after being well stirred, is set aside for twenty-four hours. At the end of this time, the phosphoric acid will be found entirely deposited in the state of double phosphate. If the soil is very poor, 20 or even 50 grms. may be taken. It may happen that, in soils produced from the decomposition of felspar, the whole of the phosphoric acid may not be extracted by aqua regia; in this case, the residue, after treatment with this solvent, is fused with a mixture of carbonates of soda and potassa, dissolved in hydrochloric acid, and, after separation of the silica, phosphoric acid may be again sought for in the liquid. It must be remembered that phosphoric acid in so insoluble a state is not of the slightest agricultural value.

(c). *Dung.*—500 grms. of the sample are weighed out, dried in the water-bath, and incinerated in successive portions.

(d). *Waters.*—Before attempting the quantitative determination of phosphoric acid in waters, a qualitative test should be applied. Add to the water a little perchloride of iron, and precipitate with ammonia. Let the precipitate stand to collect for twenty-four hours, decant off the clear liquid, re-dissolve the precipitate (which contains all the phosphoric acid) in a little hydrochloric acid, evaporate to dryness, and heat to 250° C. for thirty minutes to

separate out silica. Re-dissolve in hydrochloric acid and water, filter, and add Sonnenschein's molybdic solution. If a yellow precipitate or a yellow colouration appears, the quantitative process may be begun. 10 litres of water are evaporated down to 1 litre. Hydrochloric acid is added to the still warm liquid in quantity sufficient to re-dissolve any deposit formed; then a few drops of perchloride of iron and ammonia in slight excess. All the phosphoric acid is thrown down along with the iron. The clear liquid is decanted off, the precipitate collected on a filter, washed, re-dissolved in a little hydrochloric or nitric acid, and 5 c.c. of the citro-magnesian liquid and an excess of ammonia are added to the liquid. The analysis is then completed as above directed.

Superphosphates.

The amount of phosphoric acid existing in a soluble state in a manure may be found by dividing the amount of "neutral phosphate of lime made soluble" by 2.18. The solution of a soluble phosphate is a double process. For the aqueous solution, containing the soluble phosphoric acid, we weigh out 5 grms. of the sifted sample; it is put in a glass holding about 125 grms., covered with a little distilled water, and stirred up with a glass rod flattened at the end, so as to form a thin paste; 20 c.c. of cold distilled water are then added, the whole stirred up, and left to settle. The turbid liquid is poured into a flask marked at 100 c.c., and 10 more c.c. of distilled water are put upon the sediment, until the flask is filled and the phosphoric acid is completely extracted. When this process is at an end, the last washing should no longer reddens litmus-paper. The turbid solution is then filtered, under a bell-glass if needful.

The acid solution, containing, of course, the total phosphoric acid in the sample, is prepared by putting 5 grms. of the sample in a beaker, adding 5 grms. of pure nitric acid, digesting on the sand-bath, adding water, and exhausting as above. Each of these two solutions is then analysed separately as directed above. The amount of soluble phosphate deducted from the "total," as found in the acid solution, gives the quantity present in the insoluble state.

(To be continued).

FRESENIUS'S JUBILEE DAY.*

FRIDAY, May 3rd, being the twenty-fifth anniversary of the foundation of Fresenius's Laboratory, at Wiesbaden, there was, on that day, one of the most pleasing spectacles it has been my lot to witness. The large hall in which the jubilee ceremony took place was speedily filled. The greater part of the company consisted of the former and present students of Fresenius; there were also present officials of the state, as well as deputations from the various universities and scientific societies of Europe.

The ceremony was opened by a speech from Dr. Fresenius, giving an account of the erection and progress of his Laboratory. I will here endeavour to give a short account of this man's career. Dr. Remigius Fresenius was born in 1818, at Frankfort-on-the-Maine, where he passed the early years of his life. In 1840, he studied at the university of Bonn under Dr. Claud Marquart, from thence he removed, in 1841, to Liebig's Laboratory at Giessen, where he remained until the end of 1843, during which time he occupied the position of student, private assistant, and Government assistant at the above-mentioned laboratory. It was during his stay there that he published his first edition of "Chemical Qualitative Analysis."

About 1845, in answer to a call from the Nassau Government, he removed to Wiesbaden, where he commenced giving lectures on Chemistry, in the palace of the then reigning Duke of Nassau, who fully recognising

* Communicated by one of his Students.

his great abilities, was the means of helping Fresenius to erect this laboratory which has sent out so many good chemists, and established the reputation of their teacher as one of the most eminent analysts of the present day.

Fresenius's speech being ended, the President of the Duchy of Hesse Nassau, on the part of the Emperor, presented him with the Gold Medal for Science. From the Imperial Prince and Princess he received a laurel wreath, together with an autograph letter from the latter, which ran as follows:—

"On this your jubilee day, accept the hearty good wishes of myself and the Crown Prince. We take a sincere interest in this happy event, and beg you to accept, in remembrance of it, our enclosed portraits, and hope that they may find a place in that same room where you have received us so kindly. In conclusion, let me add my earnest wish, along with those that will be so loudly expressed to-day, namely, that you may be spared for many years hence both to Science and the Fatherland.

"VICTORIA,

"Crown Princess."

After this, the Students' Gift was presented to Fresenius. It consisted of three elegant albums, containing the portraits of his former and present pupils. Along with these was a silver fruit dish, with a Minerva statuette on the top. The whole was supported on a marble pedestal, on which was inscribed these words:—"To Privy Councillor Professor Dr. Remigius Fresenius, from his grateful students, in remembrance of the twenty-fifth year of the foundation of the Chemical Laboratory of Wiesbaden." Then came various congratulatory addresses from this town, and also from several scientific societies of Europe.

The ceremony was closed by a speech from Professor Neubauer (who is well known in England by his book, "Analysis of the Urine.") In the afternoon there was a grand dinner given to Fresenius, where more than 200 persons sat down, when his health was drunk with enthusiasm.

In closing the account of this memorable day, I only repeat the wish of all who know this great man, in saying that it is our earnest wish that his life may yet be spared for many years to come, to reap the fruit of his arduous labours.

NOTICES OF BOOKS.

Fourth Annual Report of the State Board of Health of Massachusetts. January, 1873. Boston: Wright and Potter.

It was once humourously remarked by a wicked German author that every Englishman was insane upon two questions—sanitary reform and the conversion of the Chinese. We are happy to find that the former craze, if craze it be, is spreading; public health is studied as diligently, and, to say the least, as wisely, in the United States as in England. Nor is this surprising; the same causes that have polluted the air and the waters of England are actively at work on the other side of the Atlantic. The compilers of the Report before us look forward to the day "when we shall reach the state of things at present existing in the manufacturing districts of England." "Some of the brooks which were but recently pure and undefiled are now polluted so that neither man nor beast will drink freely of them; and this change is insidiously taking place from year to year." The apathy still prevailing among a large and influential portion of the unscientific community is duly estimated:—"The temptation to cast into the moving waters every form of portable refuse and filth to be borne out of sight is too great to be resisted. It is felt as strongly by municipalities as by individuals. What becomes of this refuse lower down the stream is a matter of little concern. It is got rid of, at any rate." It is consolatory to find that our

English corporations, and, to sound a still lower depth, our metropolitan vestries, do not monopolise all the selfishness and un-wisdom of the world. The "parochial mind," it appears, clings everywhere to its characteristic vices.

A mere glance at the contents of this Report will convince the reader of its value. We have an elaborate and exhaustive paper on "Sewerage, Sewage, the Pollution of Streams, and the Water Supply of Towns"; an analysis of evidence on "Beersshops and Prohibitory Laws"; a report on the "Character of Substances used for Flavouring Articles of Food and Drink"; a paper on "Drainage for Health"; an essay on "Infant Mortality"; a chapter on the "Food of the People of Massachusetts"; a "Report on the Adulteration of Milk"; the results of a correspondence on the "Antecedents of Pulmonary Consumption"; a paper on the "Adulterations and Impurities of Food"; remarks on the "Homes of the Poor in our Cities"; a report of the "Butchers' Slaughtering and Melting Association"; and, finally, a paper on the "Health of Towns." Many of these reports treat of subjects not within our cognisance; others put forward, occasionally, views from which we most emphatically dissent, but all are the work of able, thoughtful men, and are evidently the result of research equally comprehensive and minute.

In the section on the disposal of sewage and the pollution of streams, we find the evils of neglect and the respective advantages of the "earth-closet" and the "water-closet" system very fairly stated. The ventilation of drains, the circumstances under which sewer-gases may, in spite of traps, find their way into human dwellings, the disposal of manufacturing refuse and of kitchen slops, the construction of sewers and their outlets, are all explained and described.

The feeblest portion of the Report, and, indeed, of the whole work, is the account of the various processes for the treatment of sewage adopted or proposed in England. The author, instead of depending upon his own judgment, appears to have swallowed the "Report of the Royal Rivers' Pollution Commission," "with all its blushing errors thick upon it," and without the proverbial, and, in this case, most necessary, grain of salt." To this he superadded the "Report of the British Association Committee on the Treatment and Utilisation of Sewage," and Dr. Corfield's most excellent work on the same subject. After such a course of reading, no fair estimate of the comparative merits of precipitation and irrigation could be expected. The simplicity which can still quote, in unquestioning faith, such assertion as that "The manipulations required for the extraction and drying of the A B C Company's manure are attended with a nauseous odour, and would occasion a serious nuisance if the works were situated in or near a town," and which can speak of previous sewage contamination "as a definite, determinable entity," is most refreshing. We should have given Massachusetts credit for more shrewdness. It is, however, satisfactory to find that all the analyses of waters executed for the State Board of Health have been performed by the process of Messrs. Wanklyn and Chapman, and not by that of the gentleman whom the authors characterise as "the most eminent chemical authority on the sewage question."

The following statement appears to us very questionable:—"There can be no doubt that the very extensive (almost universal) use of alcoholic drinks as an ordinary daily beverage of all classes and conditions, and of both sexes, in England, is due in part to the fact that water of unquestionable purity is so very difficult to obtain." We see no evidence that the relative consumption of alcoholic liquids is smaller in towns supplied with pure water, such as Manchester, Glasgow, or Halifax, than it is in London.

If the people of Massachusetts are about to take the prudent step of excluding polluting matter from their streams and lakes, we would beg to suggest the following

standard:—That nothing should be allowed to flow into a river containing a greater amount of putrescible impurity than does the water of the river itself. They would do well, also, in legislating concerning manufacturing refuse, to exclude copper, lead, chrome, &c., as stringently as arsenic, and not place these poisonous metals on the same footing as the comparatively innocuous iron and aluminium. Whilst unable to afford at present more space to the examination of this work, we must pronounce it a storehouse of important information, and strongly recommend its perusal to all sanitary reformers.

Manual of Chemical Analysis as applied to the Examination of Medicinal Chemicals. By F. HOFFMANN, Ph.D. New York: D. Appleton and Co., Broadway.

GENERAL treatises on chemical analysis, however ably compiled, though still necessary, are no longer sufficient for the wants of the age. Each class of chemical investigators requires a separate and especial code of instructions. The agricultural chemist, the colourist, and the metallurgist have for some time enjoyed the advantage of works of this nature. It is therefore with great satisfaction that we note the appearance of the present manual especially adapted to the requirements of the pharmaceutical chemist and the manufacturer of medicinal chemicals.

The first part of the work gives an account of the needful reagents and apparatus to be employed, with a brief systematic course of qualitative analysis and of volumetric operations. The second part enumerates the chief pharmaceutical chemicals in alphabetical order, pointing out the impurities and sophistications to which each is liable, and the most approved methods for ascertaining its quality. As a rule the processes recommended have been judiciously and carefully selected. The instructions for distinguishing the organic bases from each other, and for determining the amount of the more important,—such as morphia and quinine contained in commercial samples of the raw materials,—are full and trustworthy.

Some of the illustrations, we cannot help saying, are most needlessly repeated. Some of the synonyms of every substance are given, but this useful feature of the book might, with advantage, have been made more complete.

The work concludes with tables for the reciprocal conversion of metric and troy weights, and with a very elaborate index. We hope that its circulation, on both sides of the Atlantic, may facilitate the detection both of adulterations and of the impurities resulting from negligence, and hence tend to make these evils less plentiful.

PATENTS.

ABRIDGMENTS OF PROVISIONAL AND COMPLETE SPECIFICATIONS.

Improvements in the manufacture or composition of fuel. Langley Banks, 127, Campbell Street, Kingston-upon-Hull. November 12, 1872.—No. 3362. The invention relates to the combination of the following matters:—1st. The refuse which accumulates round the mouths of coal-pits. 2nd. Small coal. 3rd. Turf, peat, or such like matter. 4th. Mineral pitch. 5th. Coal-tar. 6th. The acum or refuse from cotton seed after obtaining oil-cake therefrom. The coal-tar and the mineral pitch are prepared by being mixed whilst hot and after being boiled in the ordinary manner in equal proportions. The two are then run together; before use they are re-boiled and mixed with the other ingredients before named. The whole are then compressed together by steam-power or otherwise, and the composition is then ready for use.

Certain improvements in the treatment of night-soil and other refuse matter. Gustav Alsing, civil engineer, 3, Bank Place, Preston, Lancashire. November 15, 1872.—No. 3412. For the purpose of fixing the ammonia contained in night-soil, sewage, or other refuse matter used as manure, or otherwise, and at the same time solidifying the said night-soil, sewage, or other refuse matter so as to render it in a convenient state for transport and immediate use I mix it with a proportionate quantity of sulphate of lime, commonly called gypsum or plaster-of-paris.

Improvements in the manufacture of steel and malleable iron, and in furnaces therefor. Friedrich Hahn, professor of chemistry, Berlin, Germany. November 16, 1872.—No. 3417. In manufacturing steel and malleable iron according to my improved process, I first melt the

iron ore or pig-iron and cause the molten cast-iron to descend through a chamber or passage which is supplied with heated air by a suitable blast, and in passing through the heated air the crude metal is fully exposed thereto, and being acted upon by the oxygen in the same is thereby decarburised and also freed from the various impurities usually existing in iron ore or pig-iron.

A new or improved varnish. Thomas Bagley, varnish maker, Birmingham. November 16, 1872.—No. 3421. This new or improved varnish has the following composition:—40 lbs. of damar gum, 10 lbs. of copal gum, 3 lbs. of kowrie gum, 84 lbs. of common resin, 10 lbs. of superfine resin, 16 lbs. of chloride of sodium, 51 lbs. of oil of turpentine, 51 lbs. of resin spirit, 570 lbs. of benzoline. In mixing and incorporating the materials the gums and the chloride of sodium are first melted and the resin afterwards added thereto. The mass having cooled to about 110° F., the resin spirit is added, and the temperature having been further reduced, the turpentine is added, and the temperature having been still further reduced, the benzoline is added, the several ingredients being thoroughly incorporated together. The varnish is then strained to complete its manufacture. This varnish hardens very rapidly, and is especially useful for varnishing metallic articles to prevent rusting or corrosion, but may also be applied to non-metallic articles, and to various other purposes.

Improvements in treating fatty materials in combination with various kinds of pitch, alkalies, and oil, also in the treatment of animal, vegetable, and mineral oils for lubricating purposes. Robert Hornby, manufacturer, Marchmont Street, Middlesex. November 19, 1872.—No. 3445. The novelty of my invention consists in the amalgamation of the ingredients for lubricating purposes, and in the use of stearine or other earthy substances as a lubricant for railway-carriage and other axles.

An improved apparatus for and method of treating wood and other similar substances for the manufacture of half-stuff and paper. Carl Dietrich Julius Seitz, analytical chemist, Edinburgh. November 19, 1872.—No. 3446. Wood is boiled in a vessel through which a constant circulation of heated caustic soda lye is effected by a pump placed between and connected to the wood-boiler and a heater.

Improvements in the preparation of autographic tracing-paper and in the fluid employed in connection with the same. Charles Ladislav Siciński, 1, Taplow Cottages, Balham, Surrey. November 19, 1872.—No. 3451. The invention is based on the principle of the reaction of chromates on gelatine, gums, and albumen, and consists in the preparation of an autographic tracing-paper and an improved ink for writing or drawing on the same in order that the said writing or design may be transferred immediately or at any subsequent period.

An improved method for purifying and amalgamating gum resins, including kauri gum. Alfred Morgan, merchant, 258, South Lambeth Road, Surrey. November 20, 1872.—No. 3460. Pulverising the gum in order to extract from it the foreign substances held in combination with it. The use of chloride of lime in solution for separating from the gum the woody particles and foreign substances usually found in it. The use of moist or wet heat and pressure for amalgamating the powdered or small gum preparatory to use.

Improvements in deodorising and purifying sewage and other excrementitious matters and in obtaining certain useful products therefrom. Edwin Hills, manufacturing chemist, Warrasb, Southampton, and Benjamin Biggs, merchant, 3, Laurence Pountney Hill, London. November 20, 1872.—No. 3464. This invention consists in treating sewage, night-soil, and other excrementitious matters so as to deodorise and purify them and to obtain ammonia and sulphur as residual products. According to one process the matters to be treated are mixed with lime in an air-tight tank. Air is then forced through the said matters, thereby precipitating the solid parts. The said air is then conveyed to a second tank carrying with it sulphuretted hydrogen and ammoniacal gases. This second tank contains sulphurous acid, through which the aforesaid gases are passed, and sulphite of ammonia and sulphur are thus obtained. Or the aforesaid gases may be passed through sulphuric or muriatic acid in the second tank to fix the ammonia and the sulphuretted hydrogen, and other uncondensed gases are afterwards passed through sulphurous acid or through hydrated oxide of iron contained in a third tank to decompose the sulphurous hydrogen and obtain sulphur. The sewage precipitate in the first tank may be used as a manure. According to another process the matters to be treated are placed in an air-tight tank and sulphurous acid forced through them to precipitate the solid parts and fix the ammonia and decompose the sulphuretted hydrogen and obtain sulphur therefrom. The sewage precipitate or sludge thus obtained may either be dried and used as a manure or it may be burnt so as to cause it to give off its sulphur in the form of sulphurous acid gas or be otherwise utilised.

Improvements in the manufacture of steel. Peter Jensen, engineer and patent agent, 89, Chancery Lane, Middlesex. (A communication from Thomas Brooks, Minerva, Ohio, U.S.A.). November 21, 1872.—No. 3477. According to one arrangement the ingredients are by preference taken in the following proportions, viz.:—74 lbs. of bar iron, 14 ozs. of tungsten, 8 ozs. of charcoal, 3 ozs. of manganese, 8 ozs. of fluor-spar, or chlorophane, and are treated as usual in a smelting-pot. When a finer quality of tool welding steel is required, 102 ozs. of calcium tungstate is substituted for the tungsten. In producing a "file steel" he uses by preference about 74 lbs. of "Bessemer" scrap or rail bar, 1½ lbs. of cast-iron, or 2 lbs. of fluor-spar, or chlorophane, ½ oz. of manganese, 1½ ozs. of charcoal, 1 oz. of bismuth, and the same is treated in a smelting-furnace. In some cases 74 lbs. of wrought bar-iron, 14 ozs. of tungsten, 14 ozs. of spiegeleisen, 8 ozs. of charcoal, ½ oz. of black oxide of manganese are employed and treated as usual in a crucible. Steel thus produced will weld without the usual chemicals employed for that purpose, will make tools capable of receiving clean sharp edges, and be perfectly malleable and tough. In the above processes the inventor prefers to use Swedish roll bar of the KB brand.

THE CHEMICAL NEWS.

Vol. XXVI. No. 709.

ON THE REDUCTION OF PURE ANHYDROUS
SESQUIOXIDE OF IRON
WITH PURE CARBON *IN VACUO*.

By JOHN PARKY.

Ebbw Vale Iron Works, Newport, Mon.

BEYOND the mere fact that carbon, in contact with the oxide of iron at a red heat and upwards, reduces the latter to the metallic state, we have little or no information as to the part which carbon takes in the reduction of oxide of iron. It has been shown by the author's previous experiments, and by others, that carbon most carefully prepared by the ordinary methods still contained volatile matter capable of evolving gas under suitable conditions, i.e., on heating *in vacuo*, or on being brought in contact at a red heat with oxides; hydrogen combining with oxygen to form water, and the remaining gases form other gaseous compounds with oxygen, the solid carbon being also taken up by the oxide in contact with it. Taking this view of the matter, it may be said the decomposition of sesquioxide of iron by the direct action of carbon only has never yet been achieved.

It occurred to the author that this might be done *in vacuo*, taking suitable precautions to secure sesquioxide of iron and carbon free from gas of any kind.

The mercury air-pump offered a ready means of doing this; and accordingly pure sesquioxide of iron and carbon were made by Mr. E. H. Morton, F.C.S., as follows:—

Pure sesquioxide of iron was prepared from pure oxalate of iron; the dried salt was heated in a combustion-tube, in a current of purified hydrogen, until complete reduction took place. The metallic iron obtained had a steel-grey colour. It was dissolved in hydrochloric acid, oxidised, and precipitated by ammonia. The precipitate was well washed a great number of times with boiling water, dried at 100°, then ignited. This was found to be quite pure, with the exception of a trace of sulphur.

Preparation of Carbon free from Volatile Matter.—This was made from white sugar, first heated until all evolution of gas had ceased, then in the full heat of a gas blowpipe, next fusing heat of iron, and lastly *in vacuo*, and kept in well-stoppered bottles.

The object being—(1) To ascertain, experimentally, that on heating carbon in contact with sesquioxide of iron, the latter was reduced; (2) the temperature at which reducing action commenced; (3) the rate of reduction at known temperatures; (4) quantity and kind of gas evolved at various degrees of heat. The author proceeded as follows:—

Expt. 1.—1 grm. of sesquioxide of iron mixed with 0.25 grm. of carbon was placed in a glass tube closed at one end, the other being drawn out and attached to the pump with water-joint, as shown in Frankland and Armstrong's memoir (*Chemical Journal*, vol. vi., p. 90). A vacuum being first formed in the cold, the part of the tube containing the mixed sesquioxide of iron and carbon was placed in a vessel of water, which was then heated to boiling; no gas was evolved, showing that the temperature was insufficient. The tube was next placed in a bath of fused lead, gas was slowly evolved, and in 7.30 hours 3.3 c.c. of gas was collected (B 760 temp. 0 deg.), which contained 87.2 per cent carbonic acid, equal (the number of c.c. of oxygen in 1 grm. Fe_2O_3 being 209.834 c.c.) 1.4 per cent nearly oxygen evolved.

Expt. 2.—The amount of carbon required for the conversion of the oxygen contained in 1 grm. of sesquioxide of iron into CO_2 being 0.1146 grm., 1 grm. of sesquioxide

of iron was mixed with 0.13 grm. of carbon, the carbon and oxide were well mixed with a spatula on a sheet of glazed paper, and transferred to a porcelain tube, the mixture being about the centre. The posterior end of the tube was closed with a well-fitting dry cork coated with melted sealing-wax, and thereby rendered impervious to air. The other end of the tube was connected with the pump by means of a pierced, well-fitting, india-rubber cork and glass tube, the cork being coated with a thick varnish. Thus arranged, on pumping, the vacuum was found to be perfect, the whole being kept *in vacuo* for twelve hours previous to heating. For heating, a small gas blast-furnace was fitted up, in which the tube was laid, the part containing the mixed carbon and sesquioxide of iron being placed so that the blast gas flame should play exactly upon the part containing the mixture.* By regulating the gas and air any desired temperature could be obtained and maintained; the temperature being estimated by putting small rods of different metals in the gas flame, regulating the supply of gas and air so as to just fuse the metals in the flame, it being assumed that the tube and its contents in the same flame had an equal temperature.

At a heat rather above the fusing-point of zinc, but below that of brass, 53.52 c.c. of gas were evolved in 7 hours 10 minutes, containing 37.15 c.c. CO_2 16.37 CO = 45.335 oxygen taken up from 1 grm. of sesquioxide of iron, or 21.605 per cent. At the end of 7 hours and 10 minutes the gas had all but ceased coming off, and only a few bubbles were collected on further heating for three hours.

The heat was now raised to *bare* fusing of brass. Gas was evolved, as nearly as could be estimated, at the rate of 5 c.c. per hour for 1 hour 15 minutes.

The heat again raised, brass readily fused, but not copper. Gas came off at nearly three times the previous rate; at the end of two hours it had nearly ceased. The heat was continued for one hour longer, but very little gas was evolved.

Heat was now raised to nearly fusing-point of copper. At this temperature gas was rapidly evolved, and for the first 3 hours and 25 minutes came off without the aid of the pump; after this the pump was required to collect the gas.

Total gas in ten hours, temperature rising from bare fusion of brass to *bare* fusing of copper, 51.273 c.c. CO_2 130.547 CO = 116.546 c.c. oxygen, taken up from Fe_2O_3 .

The total number of c.c. gas evolved in 17 hours 10 minutes was 235.34, of which 88.423 was CO_2 , and 146.917 CO , equal 161.881 c.c. oxygen from the sesquioxide of iron, leaving only 47.953 oxygen still in combination.

These experiments show—first, that at low temperatures the reducing action of carbon is slow, also that such action is not long continued; after a certain time it practically ceases altogether; but it is also clear that at low temperatures an economy of carbon is effected, the temperature not being sufficient to convert the carbonic acid first formed into carbonic oxide. Nevertheless, it is shown that, even at low temperatures a considerable amount of oxygen is liberated; thus, in 7 hours 10 minutes, nearly 22 per cent of the total quantity was evolved, and when it is considered that in reduction operations on the large scale this may be considered a comparatively short time, the reducing action of carbon on sesquioxide of iron, even at low temperatures, deserves consideration. The after trials, at temperatures below the fusing-point of cast-iron, also show that the reduction of sesquioxide of iron by solid carbon is rapidly effected. Altogether, the time, 17 hours 10 minutes, required for the evolution of 75.1 per cent oxygen is less than the time usually taken by iron ore in its descent from the top to the bottom of the blast-furnace; but it must be remembered that the *whole* of the *ore* cannot be said to be in contact with carbon in the blast-furnace, and consequently this only applies in a modified degree to the blast-furnace.

* Both ends of the tube kept cool with a small stream of water constantly running.

The author, however, wishes this to be considered as only a preliminary paper. It is intended to carry out these experiments *in vacuo* in a more complete manner, and the exact effect due to temperature will be thoroughly tested by heating weighed sesquioxide of iron and carbon in fixed baths of the metals and their alloys, from the fusing-point of zinc to that of cast-iron, taking the time required until action ceases, the amount and composition of the gases evolved, from which the amount of oxygen taken up can be readily calculated.

It is also intended to carry out a similar series of experiments with various kinds of iron ore.

Next, to test the action of carbon on Fe_2O_3 in—(1) an atmosphere of CO_2 ; (2) of CO ; notably the latter, in order that the results may be compared with those *in vacuo*.—*Journal of the Iron and Steel Institute*.

ON THE
DETERMINATION OF PHOSPHORIC ACID
IN ALL PRODUCTS OF
AGRICULTURAL AND PHYSIOLOGICAL
IMPORTANCE.

By M. JOULIE.

(Concluded from p. 310).

PART III.

To be assimilable, phosphates must be soluble in the water of the soil. But, except the acid phosphate of lime, all calcic phosphates are insoluble, or nearly so, in pure water. Even the acid phosphate is soon converted into a neutral salt by the lime in the soil. But the water in the soil is not pure, but charged with carbonic acid, and is thus able to dissolve the neutral, and even the tribasic, phosphate of lime when recently precipitated. The water in soils contains, further, salts which all, more or less, promote the solution of phosphate of lime. The humus contained in the dark coloured soil of heaths and woodlands attacks phosphates energetically; this is in part due to the presence of acetic acid in humoid matter, as proved by Déhéraïn. The assimilability of a phosphate depends on the greater or less ease with which it is attacked by the solvents just mentioned, and also on the class of solvents which it finds in any given soil. Thus, Ardennes phosphate, well ground, is assimilable with ease in recently-cleared woodlands, but useless in chalky soils where humus is wanting; hence, the value of a phosphate cannot be stated without an exact knowledge of the soil where it is to be employed. Agricultural practice recognises in recent bones more general applicability than in fossil phosphates; hence, they bring a higher price per unit. Spanish apatite in fine powder, though far richer in phosphoric acid than the phosphatic fossils of the Ardennes, is less efficacious; hence, the mere percentage of phosphates cannot determine the value of a phosphatic mineral. Hence, the rich mineral phosphates are now almost exclusively devoted to the manufacture of super-phosphate; the fossil phosphates of the Ardennes are used upon newly-cleared woodlands; whilst recent bones are applied with success to all soils. These differences depend on the state of aggregation. If phosphates are treated with an energetic solvent, like hydrochloric or nitric acid, all dissolve readily. With sulphuric acid there is a marked difference in their behaviour, whilst acetic acid separates them into two great classes. Apatites, phosphorites, and coprolites yield to this acid merely a little carbonate of lime and a trace of phosphate. Bone-products are attacked, though much less completely, if they have been ignited. Pure tribasic phosphate, recently precipitated and air-dried, dissolves almost entirely, but, if previously calcined, only about one-half is soluble. The author determined the most favourable conditions for the action of each reagent upon phosphates, and then allowed them

to act under these conditions upon a series of normal phosphates which had been previously carefully analysed. The analysis of the products of the reaction enabled him to find precisely the degree in which each had been attacked. The two reagents selected were oxalate of ammonia and acetic acid. The phosphate most easily acted on, with the exception of the soluble acid phosphate, is the neutral salt obtained by the double decomposition of chloride of calcium and phosphate of soda in dilute solutions; it contains—

It does not lose its crystalline water below 115° , and can therefore be dried at 100° without decomposition. This phosphate was taken as a standard of assimilability. By boiling oxalate of ammonia it is almost entirely converted into oxalate of lime and phosphate of ammonia. The following proportions were most favourable:—

Powdered and sifted phosphate ..	0.5 grm.
Crystalline oxalate of ammonia ..	2.0 grms.
Distilled water	150 c.c.

The whole was placed in a flask marked at 200 c.c., and boiled gently for two hours on the sand-bath, cooled, and filled up with distilled water to 200 c.c. The amount of phosphoric acid dissolved was found to be 96.85 per cent of the entire proportion present. The acetic acid used was commercial pyroligneous acid, containing 428.72 grms. of $\text{C}_4\text{H}_4\text{O}_4$ per litre. Its action upon phosphate of lime was rather hindered by heat; hence, the experiments were made at ordinary temperatures. Half a gramme of the phosphate to be examined, powdered and sifted, was placed in a flask, mixed with a measured volume of the pyroligneous acid, and shaken up. The mixture is let stand for four or five hours, with occasional shaking, and filtered. A known volume of the clear liquid is mixed with excess of ammonia. If no precipitate is formed, it is a proof that no phosphate has been dissolved; if a precipitate is formed, it is re-dissolved. To dissolve completely half a gramme of the neutral phosphate, 50 c.c. of the acid are required. All the other phosphates were treated with the same proportion and under the same conditions. A numerous series of phosphates were then submitted to these reagents. No. 1 was the neutral phosphate above mentioned. No. 2 was a precipitate formed by adding excess of ammonia to the hydrochloric solution of bone-ash, washing with much water, and drying in the air. It contained—

Phosphoric acid	24.00
Lime	28.80
Loss on ignition	47.20
	100.00

In pure tribasic phosphate, the lime would be only 28.32; the precipitate contains, therefore, lime in excess, as always happens when phosphate of lime is thrown down by ammonia in presence of excess of lime salts. The loss on ignition is water. No. 3 was a tricalcic phosphate obtained under different conditions. Bone-ash was dissolved in hydrochloric acid, precipitated with ammonia, washed by decantation, re-dissolved in acetic acid, boiled, and partially evaporated. An abundant deposit was formed, which was washed in much water, dried at 100° , and powdered. It contained—

Phosphoric acid	40.31
Lime	46.40
Loss on ignition	11.60
Chlorine	1.22
Loss	0.47
	100.00

No. 4 is the same after prolonged ignition, and containing 44.364 of phosphoric acid. These phosphates are all unequally attacked by oxalate of ammonia, and all less than the neutral phosphate. The results were—

Designation.	Phosphoric Acid.		
	In 100 kilos of sample.	Dissolved for 100 parts of Phosphate experimented on.	Dissolved for 100 parts of Phosphoric Acid present.
1. Neutral phosphate ..	39'04	37'77	96'85
2. Tricalcic phosphate, precipitated in the cold, and air-dried..	24'00	24'80	90'83
3. Tricalcic phosphate, precipitated from a boiling acetic solution	40'31	28'18	69'90
4. Tricalcic phosphate calcined	44'36	23'94	53'96

Acetic acid acted less energetically, but in the same relative order.

Nos. 5 and 6 are phosphates from two manufactories of gelatine, obtained by dissolving in dilute hydrochloric acid, and precipitating with lime. No. 7 is a solution of a mineral phosphate precipitated in the same manner. The results were—

Percentage of Phosphoric Acid in the sample.	OXALATE OF AMMONIA.		ACETIC ACID.	
	Phosphoric Acid Dissolved for 100 parts of Phosphate present.	Phosphoric Acid Dissolved for 100 parts of Phosphoric Acid present.	Phosphoric Acid Dissolved for 100 parts of Phosphate present.	Phosphoric Acid Dissolved for 100 parts of Phosphoric Acid present.
5. 36'26	34'12	94'09	26'23	72'35
6. 32'00	26'35	82'46	25'67	80'22
7. 37'05	21'84	58'98	12'95	34'95

The order of solubility of Nos. 5 and 6 is here not the same for the two reagents, whilst No. 7 shows an unexpected inferiority. Careful experiments with mineral phosphates precipitated in the laboratory, proved that this result was due, not to the origin of No. 7, but to its mode of preparation: hence, the manufacturer of precipitated phosphates can always check the value of his methods by ascertaining the solubility of the products in oxalate of ammonia and in acetic acid. Powdered bones freed from gelatine, animal charcoal, and bone-ash were next examined. Their solubility was likewise found to diminish in proportion to the elevation and duration of the temperature to which they had been submitted.

Name of Sample.	OXALATE OF AMMONIA.		ACETIC ACID.	
	Percentage of Phosphoric Acid Dissolved for 100 parts of Phosphate present.	Phosphoric Acid Dissolved for 100 parts of Phosphoric Acid present.	Percentage of Phosphoric Acid Dissolved for 100 parts of Phosphate present.	Phosphoric Acid Dissolved for 100 parts of Phosphoric Acid present.
8. Powdered bones free from gelatine	30'00	20'38	67'93	24'00
9. Animal charcoal	29'40	12'85	43'70	16'00
10. Bone-ash	34'56	11'62	34'98	24'21

Name of Sample.	GUANOS.		OXALATE OF AMMONIA.		ACETIC ACID.	
	Percentage of Phosphoric Acid Dissolved for 100 parts of Phosphate present.	Phosphoric Acid Dissolved for 100 parts of Phosphoric Acid present.	Percentage of Phosphoric Acid Dissolved for 100 parts of Phosphate present.	Phosphoric Acid Dissolved for 100 parts of Phosphate present.	Percentage of Phosphoric Acid Dissolved for 100 parts of Phosphate present.	Phosphoric Acid Dissolved for 100 parts of Phosphoric Acid present.
11. Guano from Guanape	20'27	17'56	86'66	16'89	83'33	
12. Bolivian	27'32	12'38	45'34	14'64	53'58	

Hence it appears that, if the Guanape guano is poorer in phosphates than the Bolivian, it has the advantage in solubility and assimilability.

Phosphates of the Green Sand.

Name of Sample.	OXALATE OF AMMONIA.		
	Percentage of Phosphoric Acid in the sample.	Phosphoric Acid Dissolved for 100 parts of Phosphate present.	Phosphoric Acid Dissolved for 100 parts of Phosphoric Acid present.
13. Phosphate from the Ardennes (rich) ..	23'61	8'09	34'26
14. Phosphate from the Ardennes (poor) ..	18'88	5'74	30'40
15. Russian (green and poor)	14'86	4'50	30'27

On these phosphates, acetic acid has no action. Oxalate of ammonia places them between animal charcoal and bone-ash, the exact rank which agricultural practice assigns them.

Phosphates from the Departments of Lot, Aveyron, Tarn, and Tarn and Garonne.

Name of Sample.	Percentage of Phosphoric Acid.	OXALATE OF AMMONIA.		ACETIC ACID.	
		Phosphoric Acid Dissolved for 100 parts of Phosphate present.	Phosphoric Acid Dissolved for 100 parts of Phosphoric Acid present.	Phosphoric Acid Dissolved for 100 parts of Phosphate present.	Phosphoric Acid Dissolved for 100 parts of Phosphoric Acid present.
16. Agatised phosphate; hard; powder pale yellow ..	34'50	8'72	24'60	9'55	27'60
17. Concrete; soft; powder deep yellow	16'80	5'70	33'93	5'74	34'17
18. Similar sample from another mine	20'70	6'40	30'91	5'83	28'76
19. Concrete; white and soft; powder white	31'80	6'75	21'44	6'53	20'53
20. Agatised; blue and hard; powder grey	35'60	7'08	19'88	6'75	18'96
21. Concrete; brown and soft; powder brown	21'60	3'38	15'62	2'47	11'46

These phosphates belong to the same formation, but they are mixed with variable quantities of foreign matter—such as carbonate of lime, ferruginous clay, and oxide of manganese—which modify their state of aggregation, and

consequently their solubility. They are distinguished from the nodules of the Ardennes by their greater solubility in acetic acid. They are only fit for conversion into superphosphate.

Name of Sample.	Percentage of Phosphoric Acid.	OXALATE OF AMMONIA.		ACETIC ACID.	
		Phosphoric Acid Dissolved for 100 parts of Phosphate present.	Phosphoric Acid Dissolved for 100 parts of Phosphoric Acid present.	Phosphoric Acid Dissolved for 100 parts of Phosphate present.	Phosphoric Acid Dissolved for 100 parts of Phosphoric Acid present.
22. Phosphate of Ain (Bellegarde)	16.51	4.38	26.52	0.00	0.00
23. Rhone Valley (fossils of the Gault)	23.00	5.88	25.56	0.00	0.00
24. Phosphorite (Nassau)	31.74	7.10	22.40	0.00	0.00
25. Coprolite (Cambridge)	23.80	5.20	21.84	2.25	9.46
26. Navassa phosphate	30.62	4.95	16.47	4.73	15.44
27. Nivernais phosphate	22.20	3.15	14.19	1.35	6.08
28. Apatite (Caceres, Spain)	31.14	4.10	13.16	0.00	0.00
29. Apatite (Canada)	32.01	trace	trace	0.00	0.00

The phosphates of Bellegarde, of the Rhone, and Nassau, approach the type of the Ardennes nodules by their solubility in oxalate of ammonia and their insolubility in acetic acid. That of Navassa resembles the phosphates of the Garonne. Cambridge coprolite and Nivernais phosphate belong to the type of the bone products.

Oxalate of ammonia enables us to class phosphates in a series closely approximating to that of their relative assimilability. The action of acetic acid, less powerful and general, enables us to seize some distinctions which the oxalate fails to indicate.

It is evident that the agricultural value of phosphates for use in an undissolved state depends more on their solubility, and consequent assimilability, than on their percentage of phosphoric acid.

CONVERSION OF THE SULPHATES OF THE ALKALIES INTO THE CARBONATES, TARTRATES, &c., IN THE MOIST WAY.

By J. LAWRENCE SMITH.

HAVING had occasion more than once to convert small quantities of the sulphates of the alkalies into carbonates, I have for several years employed a process that has been found both certain and convenient: in some recent investigations it has been used, and as it has never been described it may not be unimportant to explain the nature of the process and its results. The agent used to produce the conversion is carbonate of baryta, made by precipitation: where precise results are required the carbonate should be prepared by carbonate of ammonia. The manner of producing the decomposition is as follows:—Dissolve the sulphate of potash in water, using about 20 or 30 grms. of water to every gramme of the sulphate, and saturate the solution with carbonic acid by passing a current of carbonic acid into it; or, what is better, dissolve in the beginning the sulphate in water already saturated with carbonic acid; now add to this solution precipitated carbonate of baryta, in the proportion of about 1½ of the carbonate to 1 part of the sulphate. It is always best, in adding the carbonate, to rub it up in a mortar with a little water, so as to form a thick cream, for by so doing it mixes well in the solution.

This operation is performed in a bottle that can be well corked with a cork or gum stopper; now agitate the bottle frequently, or, what is still better, attach it to a piece of machinery that will agitate the bottle. Many laboratories have such, and it is a very useful one in many experiments. In a longer or shorter space of time, the decomposition will be completed, pour the solution into a capsule and heat to the boiling-point; the solution will then contain only carbonate of potash.

The reaction is readily understood. The carbonic acid in the water dissolves a little carbonate of baryta, which is immediately re-precipitated in the form of sulphate, carrying down a portion of the sulphuric acid of the soluble sulphate, and replacing the same with carbonic acid; this

is rapidly repeated through the agency of the free carbonic acid, until the decomposition of the sulphate is complete.

Among many experimental results, I will give the following:—Five grms. of the sulphate of potash, dissolved in carbonic acid water, to which was added 7 grms. of precipitated carbonate of baryta, after four and a half hours' shaking (being attached to a suitable piece of machinery), on testing showed not a trace of sulphuric acid, care being taken to wipe the neck of the bottle near the end of the stopper before pouring out the liquid.

Other experiments, varying in proportion, gave similar results. I tried to substitute the natural for the precipitated carbonate of baryta, but with very unsatisfactory results.

Directions for the Conversion of the Alkaline Sulphates into Tartrates, Oxalates, &c.—As the tartrate and oxalates of baryta are but very slightly soluble in water, we cannot form the alkaline salts of these acids by direct double decomposition of the sulphates of the alkalies and the tartrate, &c., of baryta, as in forming the alkaline chlorides from the sulphates; but it is easily done by the following indirect process:—

Add to the alkaline sulphates in solution, in a porcelain capsule, carbonate of baryta rubbed up into a thick cream, in the proportion of about 5 of the sulphate to 7 of the carbonate of baryta; heat the mass, and add, little by little, the requisite quantity of tartaric or oxalic acid. Solution of the baryta and precipitation of the sulphuric acid take place rapidly, and the decomposition is soon completed.

I have used this process of forming the bitartrates in the process of separating potassium, rubidium, and cesium, that were in the form of sulphates.

The Carbonates of the Alkalies can also be formed by first forming these organic salts from the sulphates, evaporating the solution to dryness, and burning the residue; in fact, I frequently find it more convenient to convert the sulphates of the alkalies into the carbonates by this last instead of the first process. And, finally, I would remark that, where magnesia is present with the sulphates, this is also separated from the alkalies.—*American Chemist.*

PROCEEDINGS OF SOCIETIES.

CHEMICAL SOCIETY.

Thursday, June 19, 1873.

Dr. ODLING, F.R.S., President, in the Chair.

WHEN the minutes of the preceding meeting had been confirmed, and the donations made to the Society announced, the name of John Douglas, Esq., was read for the first time. For the third time, those of Messrs. Walter Odling, Archibald Kitchin, James Emerson Reynolds, and Robert Wild, who were then balloted for and duly elected. The first paper, by J. H. GLADSTONE, F.R.S., and

A. TRIBE, entitled "*Researches on the Action of the Copper-Zinc Couple on Organic Bodies*" (III. "On Normal and Isopropyl Iodides"), was read by Dr. Gladstone. The action of isopropyl iodide on the dry couple at 50° commences after a few minutes, gases are evolved, and the liquid residue in the retort, when strongly heated over a flame, evolves more gas, and at the same time a small quantity of a liquid distills over, apparently containing zinc-isopropyl. As it had been found that more zinc-amyli was produced from the corresponding amyl compound when the contents of the flask were distilled *in vacuo*, the same method was adopted with the isopropyl iodide; and in this case, also, the product obtained was considerably larger. Careful examination and analyses of the gases evolved showed that they consist of nearly equal volumes of propylene, C_3H_6 , and hydride of propyl, C_3H_8 . The two reactions, $Zn + 2C_3H_7I = ZnI_2 + C_3H_6 + C_3H_8$ and $2Zn + 2C_3H_7I = ZnI_2 + Zn(C_3H_7)_2$, go on simultaneously at 50°, and when heated to 130° most of the $Zn(C_3H_7)_2$ splits up into $Zn + C_3H_6 + C_3H_8$. As was to be expected, the action of the couple on the iodide in the presence of water or alcohol gave propyl-hydride, C_3H_8 , the action being more rapid with the alcohol. Experiments similar to the above were also made with zinc-foil and granulated zinc, but in both cases the action was very much more sluggish, and required a higher temperature than when the couple was employed. In the investigations with the normal propyl-iodide it was found necessary to heat the iodide with the dry couple to 80° before any action took place; at 109° the action was much more rapid, and but little gas was evolved. On strongly heating the product in a current of carbonic anhydride, a large quantity of zinc-propyl passed over, which, on rectification, distilled almost entirely between 146° and 148°. When pure, it is a colourless mobile liquid, slightly denser than water, and boiling at about 146°; exposed to the air, it takes fire spontaneously and burns with a white flame. The action of the couple on the normal iodide in the presence of water or alcohol yields propyl-hydride, but the action is much less energetic than in the case of the isopropyl compound. These results entirely agree with the evidence already existing of the comparative instability of the isopropyl compounds. The authors conclude with some additional notes on the couple, describing the most advantageous way of preparing it.

The PRESIDENT, having thanked the authors for their valuable communication, enquired whether the copper took any part in the reaction, or whether alloys had been tried, to which Mr. Tribe replied that the copper had no direct action, and that brass had been tried by Dr. E. T. Thorpe, but was without effect.

The next paper, "*On the Influence of Pressure on Fermentation*" (Part II. "The Influence of Reduced Atmospheric Pressure on Alcoholic Fermentation"), was read by the author, Mr. HORACE T. BROWN, who, after referring to his former paper, proceeded to describe the methods employed, and the precautions necessary to ensure concordant results in ascertaining the amount of alcohol and carbonic anhydride produced by the fermentation of malt-wort and solutions of cane sugar under diminished pressure. He prefers determining the carbonic anhydride by the loss of weight, or by absorption by potash and soda-lime, as being more accurate than the measurement of the gas evolved. A consideration of the tabulated results obtained in this way shows that diminished pressure retards the progress of the alcoholic fermentation in a remarkable way, although there does not seem to be any simple relation between them. It is certain, however, that under diminished pressure less sugar is decomposed than during an equal time at the ordinary pressure, and that the proportion of the carbonic acid to the alcohol produced is greater. This difference was not due to any injury of the yeast cells caused by the removal of the pressure, but appears rather to be an exemplification of Sorby's law, "that pressure weakens or strengthens chemical affinity, according as it acts against or in favour

of the change of volume," since the author has proved that there is a decided contraction in volume during the alcoholic fermentation. The formation of acetic acid noticed in Part I. of this memoir the author finds to be derived directly from the sugar.

After the PRESIDENT had thanked the author in the name of the Society,

Mr. BEANES said he would like to hear from the author of the paper whether he had tried fermentation under pressure, because in July last he (Mr. Beanes), during some investigations on saccharine solutions, had occasion to place a saccharine solution of 1050 sp. gr., while in a state of fermentation, under a pressure of 36 atmospheres for two days. He found, at the end of that time, on testing it, it marked 1030 sp. gr.; while another portion of the same liquid, which had not been under pressure, marked 0.996. He thought it peculiar that the same results, viz., a decrease of fermentation, as described by the author of the paper, should be obtained by a partial vacuum, while he (Mr. Beanes) had obtained the same result by an increase of pressure.

A paper "*On Cymene from Different Sources Optically Considered*" was then read by the author, Dr. J. H. GLADSTONE, in which he communicated the results of his optical examination of the cymenes from various sources, recently described by Dr. C. R. A. Wright, which are practically the same for each, their specific refractive energy being 0.55, and their mean refraction equivalent 75.1, the difference of the extremes not being greater than that usually observed between different specimens of the same hydrocarbon. This equivalent, calculated with the common refraction equivalents for carbon (5) and hydrogen (1.3), would give 68.2; thus all these specimens of cymene showed a higher equivalent characteristic of the great aromatic group. This is particularly interesting, as some of them were prepared from substances which do not exhibit this abnormal influence on light, affording additional evidence that the retarding power of the carbon in such bodies as these does not arise from any particular internal structure capable of being transmitted from one compound to another.

After the usual vote of thanks to the author, Dr. ARMSTRONG observed that Landolt had found that, although the refraction equivalent was too high in aromatic bodies when calculated from the empirical formula, yet if in the rational formula the ordinary value for carbon was taken for the substituted radicals, and a higher one for the C_6 in the benzol nucleus, concordant results were obtained.

Dr. GLADSTONE replied that he believed he was the first to point out this, but at present, although it was true for certain compounds, more data were necessary to fix the value for the carbon in the nucleus.

Dr. C. R. A. WRIGHT said it was probable a correlation between this and other physical properties of bodies would be found, as, for instance, in the different amount of heat given out by isomeric hydrocarbons on combustion; although the results were at present incomplete, he had found this to be the case with those of the series $C_{10}H_{16}$.

A "*Note on the Action of Bromine on Alizarin*," by W. H. PERKIN, F.R.S., was then read by the author. Bromine does not act readily on dry alizarin; but, when the two substances are heated to about 170° with carbon disulphide, a brominated alizarin is produced, which, after crystallisation from glacial acetic acid, is obtained in tufts of orange-red coloured needles having the composition $C_{14}H_7BrO_4$. It dissolves in caustic alkalis with a blue-violet colour, similar to that obtained with alizarin, and giving a similar absorption-spectrum. Brom-alizarin dyes mordanted fabrics a redder violet with iron, and a browner red with alumina mordants, than is obtained with pure alizarin. Heated with acetic anhydride, it forms *diaceto-bromalazarin*, $C_{14}H_5Br(C_2H_3O)_2O_4$, a yellow crystalline substance.

After the usual vote of thanks, a memoir "*On some Oxidation and Decomposition Products of Morphine Derivatives*," by E. L. MAYER and C. R. A. WRIGHT,

D.Sc., was read by the latter. The authors state that, when apomorphine hydrochloride is heated with an excess of a solution of potassic hydrate, the precipitate at first produced is rapidly dissolved, and the solution acquires a dark colour, from absorption of oxygen. On acidifying it with hydrochloric acid and agitating with ether, a peculiar colouring matter is extracted; the ethereal solution, agitated with an alkaline solution, colours the latter grass-green, and on neutralising with hydrochloric acid indigo-blue flakes are precipitated, having the composition $C_{40}H_{34}N_2O_7$. Diapomorphine and deoxymorphine also yield this blue product when treated with potassic hydrate, but the "tetra" series and the monomorphine derivatives do not—the latter giving methylamine and pyridine, the "tetra" bodies methylamine only and no pyridine. A note to this paper, by Dr. Wright, gives the properties of some colouration products obtained as precipitates by the treatment of certain codeine and morphine derivatives with argentic nitrate and nitric acid. He mentions, as a remarkable fact, that the mother-liquors from which they had been deposited when distilled with caustic potash, yielded methylamine in the case of the morphine compounds, and none in the case of the codeine derivatives, although codeine is methyl-morphine.

Thanks having been returned to the authors for their paper, Mr. R. WARINGTON read his communication "On the Decomposition of Tricalcic Phosphate by Water." The author, after noticing that it had been observed long ago that the mono- and di-calcic phosphates are decomposed when boiled with water, drew attention to the fact that the tricalcic salt is likewise decomposed under similar circumstances. On boiling carefully-washed pure tricalcic phosphate with distilled water for two hours, the solution becomes distinctly acid, and on pouring off the water, and repeating the process ten or twelve times, a compound was at last obtained which had the composition $3(Ca_2P_2O_8)CaOH_2O$, corresponding to apatite, in which the fluoride or chloride of calcium is replaced by the hydrate. The author concluded his paper by some remarks on the solubility of tricalcic phosphate in cold water.

The PRESIDENT then thanked the author for his paper, and for drawing their attention to the formation of this quasi-apatite.

Mr. WARINGTON, in reply to a question of Mr. J. NEWLANDS, said that the pure tricalcic phosphate was prepared from a solution of disodic phosphate, to which an equivalent of ammonia had been added by precipitating it with pure calcic chloride.

Dr. H. E. ARMSTRONG then read a paper entitled "Communications from the Laboratory of the London Institution" (No. XII. "On the Nature and some Derivatives of Coal-Tar Cresol," by H. E. Armstrong and C. L. Field. This investigation has for its object the comparison of the haloid and nitro derivatives of cresol and phenol; and for this purpose the authors converted the crude coal-tar cresol, boiling between 190° and 205° , first into the sulphonic acids, and then into the corresponding potassic salts, of which they have succeeded in isolating two, viz., a sparingly soluble one, $C_7H_7O(SO_3K) + 2aq$, and a very soluble salt, $C_7H_7O(SO_3K)$; the former of which yields a very difficultly soluble baric salt when precipitated with baric chloride, and is doubtless identical with Engelhardt and Latschinoff's paracresol-sulphonic acid. The mother-liquors appear to contain a third salt, which has not yet been examined. Both these acids yield mononitro derivatives by the action of nitric acid, which are converted into dibromonitrocresols by treatment with bromine. When the crude cresol is acted on by dilute nitric acid, and the product distilled in a current of steam, crude nitrocresol passes over as a yellow oil, whilst a black residue is left in the retort. The oil readily yields a dinitrocresol melting at about 82° , and forming magnificent red potassium and sodium compounds; it is apparently identical with the dinitrocresol obtained by the action of nitrous acid on toluidine.

The eighth communication was "On a New Tellurium Mineral, with Notes on a Systematic Mineralogical Nomenclature," by J. B. HANNAY. Whilst examining a specimen of arsenical iron pyrites, the author discovered in it some metallic tellurium, and also a substance in scales resembling specular iron ore. The latter, on examination, was found to contain arsenic, tellurium, and sulphur, in the proportions corresponding nearly to the formula $Te_2As_2S_7$. After a few remarks on the want of a systematic nomenclature in mineralogy, the author calls the new mineral "arsenotellurite," proposing to name minerals according to the principal constituents—thus, for example, limestone would be "calcite;" and when there are many minerals having the same principal constituents, to add a distinguishing prefix—thus, agate would be called "concentric ferruginous silicite," and so on. A long list of minerals, with the proposed new names, is appended to the paper.

The following paper, a "Note on Relations among the Atomic Weights," by J. A. R. NEWLANDS, was then read by the author:—In the June number of the *Journal of the Chemical Society* is a paper by L. Meyer, "On the Systematisation of Organic Chemistry," in which reference is made to M. Mendelejeff as having shown that certain properties of the elements appear "as a regular periodical function of the atomic weight, if the elements are arranged in the natural system, or according to the numerical values of their atomic weights." Now, in a paper read before this Society on March 1st, 1866, I showed that, when "the elements were arranged in the order of their atomic weights, a simple relation existed between them, those belonging to the same group standing to each other in a relation similar to that between the extremes of one or more octaves in music." I had also previously published the same statement in the *CHEMICAL NEWS*, vol. x., p. 94, and on other occasions. As my paper was not printed in the *Journal of the Chemical Society*, and therefore a question of priority may arise, I have to request, as a simple matter of justice, the insertion of this brief note in the Society's *Journal*.

The PRESIDENT said the reason why Mr. Newlands's paper on this subject in 1866 had not been published by the Society was that they had made it a rule not to publish papers of a purely theoretical nature, since it was likely to lead to correspondence of a controversial character.

The PRESIDENT then adjourned the meeting till after the recess, congratulating the members on the flourishing state of the Society and the number and importance of the papers which had been read there during the session.

CORRESPONDENCE.

ACETAMIDE AND ETHYLATE OF SODIUM.

To the Editor of the *Chemical News*.

SIR,—It is evident that Mr. Wanklyn does not know what he is talking about when he makes such a communication as that which I read in your last number, p. 302. Those acquainted with the substance of my paper know that, when sodium alcohol and acetamide are heated together, less than 5 per cent of the ammonia obtainable from acetamide is given off, and that the amount of ammonia depends upon how far moisture gains access to the materials. The conclusions I arrived at were that perfectly dry acetamide and dry sodium alcohol yield no ammonia of any kind, neither do they produce a new compound. This was not apparent from your reporter's notice; I therefore ask you to be so good as to publish this.—I am, &c.,

W. N. HARTLEY.

King's College, London,
June 22, 1873.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Under this heading will be found an encyclopædic list of chemical papers published abroad during the past week, with abstracts of all susceptible of advantageous abridgment. The two half-yearly volumes of the CHEMICAL NEWS, with their copious indices, will, therefore, be equivalent to an English edition of the "Jahresberichte."

NOTE. All degrees of temperature are Centigrade, unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances de l'Académie des Sciences, June 2, 1873.

Action of the Chief Derivatives of Amylic Alcohol upon Polarised Light.—I. Pierre and E. Puchot.—Amylic alcohol has an action upon polarised light resembling that of a solution of sugar of 1.4 per cent, but of an inverse direction. The authors found, in all the experiments to which they submitted the pure amylic alcohol of fermentation, no indication of the second amylic alcohol pointed out by Pasteur. The action of ordinary amylic alcohol upon polarised light is increased one-third by the addition of about 6 per cent of water. Amylic alcohol, reproduced from its ethers, or obtained as the residue of an incomplete oxidation, does not appear to have undergone any appreciable modification either in the direction or the intensity of its action upon polarised light. This is not the case with its ethers, nor with the compounds formed under the oxidising influence of a mixture of sulphuric acid and bichromate of potash, along with the necessary amount of water. The first of these oxidation products, amylic aldehyde, turns the plane of polarisation in an opposite direction; in the same, namely, as would be produced by crystallised sugar. With the pure aldehyde this deviation is equal to that which would be produced by a solution of crystallised sugar at 1 per cent. Its degree of purity has a great influence on the extent of deviation. A sample of crude aldehyde, saturated with water, gave a deviation three times greater than does the pure substance. The presence of the water was, however, found not to be the cause of this increased action, since a sample of pure aldehyde saturated with water exerted a rotatory power decidedly inferior to that of the anhydrous aldehyde. The second product of oxidation, valerianate of amyl, (isomeric with the aldehyde above mentioned) causes a deviation in the same direction—but seven times greater—equal to that of a solution of crystalline sugar of 6.6 per cent. The results obtained with the amylic compounds are represented in the subjoined table; the sign + being attached to the deviations similar in direction to crystalline sugar, and – to those in the inverse direction:—

	Sp. Gr. at 0° C.	Boiling- point. Degrees.	Deviation. Degrees.
Valerianate of amyl ..	0.8740	190.0	+ 40.0
Butyrate of amyl ..	0.8769	170.3	+ 8.5
Valerianate of butyl ..	0.8884	173.4	+ 3.0
Valerianate of propyl ..	0.8862	157.0	+ 9.0
Valerianate of ethyl ..	0.8860	135.5	+ 12.5
Valerianate of methyl ..	0.9005	117.5	+ 8.5
Valerianic acid (mono- hydric) ..	0.9470	178.0	+ 5.0
Anhydrous amylic alcohol	0.8255	130.0	– 8.5
Do. do. with 6 per cent water ..	—	—	– 11.0
Amylic aldehyde (pure) ..	0.8209	92.5	+ 6.0
Do. do. crude (hydrated)	—	—	+ 18.0

Two active isomeric bodies like valerianate of butyl and butyrate of amyl are not necessarily equal in rotatory power. There does not seem to exist any definite relation between the rotatory power of two isomeric active bodies and their respective specific gravities.

Detection and Determination of Sulphate of Lead in Commercial Chromates of Lead.—E. Duvillier.—The methods used to decide on the purity of a chromate of lead do not indicate whether sulphate of lead be present or absent. The author heats gently, in a flask of sufficient size, 1 part of the sample of chromate with 2 to 3 parts of nitric acid at 1.420° sp. gr., 1 to 2 parts of water, and $\frac{1}{4}$ of alcohol. The reaction is very strong, and must be moderated by reducing the heat. When the violent action has subsided, heat is still applied till all nitrous fumes have disappeared. In the flask will be found a violet liquid—a mixture of nitrate of lead and nitrate of chrome—and a white precipitate of nitrate of lead, along with which sulphate of the same metal may be present. Water is added and the whole boiled. If no sulphate is present the whole dissolves; but otherwise sulphate of lead remains insoluble. To determine its amount the whole is evaporated to dryness to expel nitric acid, and the products of the oxidation of alcohol, care being taken not to heat so strongly as to decompose the nitrate of chrome. On treating the residue with water the sulphate is left undissolved. This method is applicable to all chromates.

Action of Nitric Acid upon Chromate of Lead.—E. Duvillier.—In allowing nitric acid, diluted with 1 to 2 volumes of water, to act at the boiling-point upon pure chromate of lead the liquid took the colour of chromic acid, and preserved it on cooling, although the bulk of the chromate of lead remained unchanged. On concentration crystals of nitrate of lead were deposited. The mother-liquor evaporated to dryness yielded a solution of chromic acid nearly pure, but representing a very small part only of the chromic acid present in the quantity of chromate employed. The action of the nitric acid is, therefore, analogous to its behaviour with chromate of baryta. With the latter, however, the amount of water is immaterial, whilst if water be added to a solution of chromate of lead in nitric acid this salt is precipitated. On treating the chromate of lead with double its weight of nitric acid we obtain a solution of chromic acid containing only 2 per cent of lead oxide. Nitric acid, therefore, resolves chromate of lead into chromic acid and into nitrate of lead, which is precipitated at a boiling heat in presence of the excess of nitric acid employed.

On a Base Isomeric with Piperidine, and on the Nitro Derivatives of the Hydrocarbons of the Formula $C_{2m}H_{2m}$.—H. Gell.—Meyer and Stuber have lately prepared isomeric compounds of the nitrogenous ethers formed by wood-spirit, alcohol, and oil of potatoes. These new substances behave like nitro derivatives of hydrocarbons of the general formula $C_{2m}H_{2m+2}$. This discovery of these compounds tends to disprove the essential difference which had been assumed between these carbides and those of the aromatic series, $C_{2m}H_{2m-6}$, the only group whose nitro derivatives were known. The author endeavoured to obtain analogous compounds of another family, still resulting from the substitution of an equivalent of hyponitric acid for one of hydrogen. He sought to prepare the nitro derivatives of the hydrocarbons $C_{2m}H_{2m}$. Having added to nitrethane the quantity of potassa dissolved in alcohol necessary for its transformation into potassic nitrethane, it was placed in contact with an equivalent of iodide of allyl. On adding water to the filtrate an oily liquid was obtained which could not be purified for analysis as it was decomposed on volatilisation. On treating it with hydrochloric acid and fragments of zinc the insoluble oil disappeared, and on distilling the residual liquor with an excess of potassa a colourless liquid was obtained which, on the addition of some fragments of potassa, gave an odour of piperidine. The new substance differs from that base in several important respects. It boils at 85°, and its isomer at 106°. It is soluble in water and alcohol, and combines energetically with acids. If poured upon bisulphide of carbon it gives rise to a brisk reaction, but the liquid does not crystallise

on cooling like piperidine. The author concludes that it is a primary mono-amine of the formula—

Note on the Transit of Venus in 1882.—M. Pinseux.—The author gives a number of particulars as to the circumstances of observation. He points out that the shortest transit will be observed in the neighbourhood of New York, and the longest (in accessible regions) in Terra del Fuego and adjacent islands, the difference of duration being about sixteen minutes. The most retarded ingress will be observed in Canada and New Britain; the most accelerated in the island of Kerguelen, between which and Montreal the difference will be more than fifteen minutes. The most accelerated egress will be observed in the Antilles and Euzana; the most retarded in the eastern part of Australia, *e.g.*, Sydney; the difference from the time of ingress being about fifteen minutes. The determination of parallax by observations of contact will be in less advantageous circumstances than in 1874. In the latter case, with accessible regions the differences of duration of transit reach twenty-six minutes, the differences of times of ingress twenty-one minutes, and those of times of egress eighteen minutes; while in 1882 the differences will be reduced, the first to sixteen and the two others to fifteen minutes. Instead of observing the hours of contact, however, the parallax might be deduced from measurements made during the transit, and giving at various instants either the angular distances of the centres of Venus and of the sun, or the angle of position of Venus. M. Pinseux illustrates these points.

Trial during a Solar Eclipse of the New Spectroscopic Method Proposed for the Approaching Transit of Venus.—P. Secchi.—His method is as follows:—A highly dispersive direct-vision prism is placed about 25 c.c. before the slit of an ordinary spectroscopic tube on the same tube. This gives in the plane of a slit a coloured image of the sun in the form of a very impure spectrum. The rays transmitted thence through the spectroscopic form in the field of the small telescope a very distinct solar image, in which not only the border of the disc, but also the spots and the faculae are quite visible. The sun is seen, in fact, as with coloured glass. When the image is received so that it is formed by red rays, then by putting the Fraunhofer line C near the sun's border at the exterior, one sees the chromosphere as a bright line separated from the solar disc by a distance equal to the height of the chromosphere; but one may at will displace this line according to the part of the chromosphere to be observed, even to contact with the sun's border. Hence, when the dark star covers the chromosphere in points situated in the field of the telescope, one will see this bright line interrupted, and be advised that the star approaches contact. One may then follow its movement by placing the slit near the border, and as the border itself is distinctly seen may estimate very exactly the instant in which (the line disappearing) the border of the dark star eats into the disc of the bright star. P. Secchi observed the recent eclipse thus, and found the results fully up to his expectations. P. Rosa and P. Ferrari also made observations at the same time; the former with a Weil refractor, magnifying 80 times, the latter with a Cauchoix telescope magnifying 120 times; and from comparison of the mean result with P. Secchi's it appears that first contact was anticipated by P. Secchi by 11.9 seconds, while the egress was retarded by 12.2 seconds; the method gives more precision. Comparing his results with those of M. Respighi, who used an ordinary spectroscopic according to a method proposed by Zollner, P. Secchi finds M. Respighi in advance of him at the commencement and behind him at the close, the difference of duration being 34.2 seconds; but he gives reasons for thinking this result excessive; chiefly the sun's border seen by Zollner's method is imperfectly defined.

The writer makes these suggestions:—(1) For the first notice of the phenomenon use the ordinary spectroscopic as for observation of protuberances; (2) having ascertained the ingress of Venus on the chromosphere mount the prism before the slit to obtain a distinct and direct solar image in the field of the spectroscopic (an objective prism is preferable to a direct-vision prism); (3) for the second interior contact use either this method or the ordinary.

Action of the Electric Fluid on Flames, Liquids, and Powdery Substances.—Second note by M. Neyeureuf.—The writer examined flames containing no solid particles. In pure hydrogen there was a sensible attraction by a negative point; in carbonic oxide and sulphide of carbon the attraction was more marked, and to both points. Alcohol behaves like ordinary gas. Retreat of the flame is most marked with essence of terebenthin (burnt in a lamp). If the electric point be directed normally to the surface of liquids in a conducting cylindrical capsule an umbilicus is produced for both fluids in water, oil, sulphide of carbon, essence of terebenthin. With badly conducting liquids, if one withdraws the point after having immersed it some millimetres, a liquid cone remains adherent as long as the electricity passes. Few powders give distinct effects. The blue sand used for drying with is best. Either electric point held a little way off produces centrifugal effects, while if the negative point be held very near there is a centrifugal aspiration. On contact one may, as with liquids, raise and maintain a cone of grains during passage of the current.

Molecular Rotation of Gases.—M. Hinrichs.—In the molecular theory of gases only the movements of translation have been considered, and as if these molecules were small globes perfectly elastic; whereas they are composed of several atoms held at some distance from each other. The author deduces from mechanical laws that these non-globular molecules have a movement of rotation about the natural and principal axis, for which the moment of inertia of the molecule is a maximum. A knowledge of the moment of inertia of molecules has led him to calculate the boiling-points of isomers, and details will be given in his forthcoming work on molecular mechanics.

General Results of Analysis of the Glycerian Springs in the Island of San Miguel (Azores).—M. Fouqué.—Chemical analysis reveals in all the waters of San Miguel the original existence, but in various proportions, of saline compounds identical with those obtained by condensing the fumes of a volcano in action, or lixiviating cold lava; and also the presence of the most common volcanic gases.

Berichte der Deutschen Chemischen Gesellschaft zu Berlin,
May 26, 1873.

Aromatic Amide Acids with Alcohol Radicals.—Peter Griess.—The author has previously shown that in certain aromatic amide acids 1, and also 2 atoms of hydrogen can be easily replaced by alcohol radicals. He has since attempted to substitute a third atom in the same manner, and in some cases successfully. The compounds thus obtained differ very essentially from the amide acids previously described, and containing 1 or 2 atoms of an alcohol radical. The latter still possess the double attributes of acid and base, whilst the amide acids with 3 atoms of an alcohol radical have entirely lost the power of forming metallic salts, and, strictly speaking, cannot be classed as acids. They behave more like organic bases, and seem most closely connected with a little known class of basic bodies, to which Liebreich's oxyneurine and Scheibler's betaine, $\text{C}_3\text{H}_{11}\text{NO}_2$, belong. The first of the compounds obtained, trimethyl-benzo-betain, $\text{C}_{10}\text{H}_{13}\text{NO}_2$, forms small white acicular crystals containing 1 atom of crystalline water, deliquescent in the air, insoluble in ether, very soluble in alcohol, of bitter taste, and without reaction upon vegetable colours. If heated alone to fusion

it is transformed into its isomer, dimethyl-amido-benzoic acid—

a liquid of faintly aromatic odour and yellowish colour, insoluble in water. Another compound of this class, trimethyl-anisbetaine, $\text{C}_{11}\text{H}_{15}\text{NO}_3$, forms large vitreous prisms, containing 5 atoms of crystalline water. It is easily soluble in water, especially if hot, sparingly in alcohol, and insoluble in ether. At elevated temperatures it is entirely resolved into dimethyl-amido-anisic acid—

a yellowish fluid of faint aromatic odour, insoluble in water, and boiling at 288° .

On Diallyl, and on Attempts to Prepare Allyl-Benzol.—R. Wagner and B. Tollens.—The authors have attempted unsuccessfully to substitute allyl for hydrogen in benzol. In course of their researches they obtained the tetrabromide of diallyl, $\text{C}_6\text{H}_{10}\text{Br}_4$, in four-sided prisms of camphor-like odour, and fusing at 62.5° to 63.5° . As its melting-point is given at 37° the cause of the discrepancy was examined. The authors prepared diallyl by Oppenheim's method (heating the allyl-iodide of mercury with solution of cyanide of potassium) and obtained a product boiling at 58° to 60° . On the addition of bromine a product was obtained, which behaved quite similarly to that prepared by means of the bromide of allyl.

Note on the Detection of Sulphur Compounds by Means of the Blowpipe.—B. Tollens.—One of the simplest methods of testing substances for sulphur compounds is to heat them upon charcoal with soda in the inner blowpipe flame. Remarkably enough it is nowhere pointed out that this test must be performed not with the flame of coal-gas but with an oil-lamp or a candle. Coal-gas contains so much sulphur that soda upon which its flame has been driven for a minute blackens silver strongly, which is never the case with the flame of a candle.

Crystallographic Examination of the Derivatives of Naphthalin.—C. Hintze.—The author, having undertaken a revision of Laurent's labours in the same field, which he pronounces "totally useless for science," remarks that in the substitution of chlorine for hydrogen in the tetrachloride of naphthalin the angles of one crystal zone ($\beta:\beta$) remain almost equal, just as has been shown by Groth to be the case with the derivatives of benzol. Here also, therefore, the morpho-trophic action extends only in certain crystallographic directions, with the distinction that this action is stronger in the derivatives of benzol than with those of naphthalin. This fact agrees perfectly with Groth's view that the morpho-trophic action of a substance depends not alone on its chemical nature, but on the structure of the compound into which it enters by way of substitution. Elements are often isomorphous in complex compounds, but not in those of more simple structure.

On Ceanthyllic Acid and Normal Heptyl Alcohol.—H. Grimshaw and C. Schorlemmer.—Comparative examination of the ceanthyllic acid obtained from ceanthol and that prepared from normal heptane gave the following results. The ethylic ether of the acid from ceanthol is a liquid of a pleasant fruity smell, boiling at 186° to 188° . The barium salts of the two acids have the same crystalline form and the same solubility in water. The calcium salts contain 1 atom of crystalline water, and are equally soluble, both forming slender needles arranged in tufts. The copper salts are obtained as somewhat soft precipitates, which on standing become granular. They are insoluble in water, but soluble in absolute alcohol. On evaporating the solutions the salt obtained from ceanthol separates out in small green needles or prisms. On the other hand, that obtained from heptane separates first in a

liquid state and then dries up to an amorphous mass. The copper salt of Franchimont's heptylic acid was likewise separated at first in little drops, which congealed to crystals. In other respects the compounds obtained by the authors were very similar to the corresponding salts of heptylic acid. Whether the distinctions observed in the cupric salts are essential must be determined by further experiment. Ceanthyllic acid indubitably belongs to the normal series, and as its aldehyde is readily obtained it forms the best material for preparing the normal heptyl compounds hitherto scarcely known.

Affinity of Bromine for Oxygen.—H. Baumhauer.—Thomsen, in an essay on the affinity of oxygen for chlorine, bromine, and iodine, has concluded from thermo-chemical determinations that—in opposition to the prevailing opinion—the affinity between the constituents of bromic acid is considerably less than that between the constituents of chloric acid. This result he pronounces unexpected. In fact several manuals of chemistry state that bromine expels chlorine from chloric acid with formation of bromic acid (see Roscoe's "Outlines of Chemistry"). The author heated a solution of chlorate of potassa with bromine, but on evaporating the residue no bromate could be detected. Neither was any bromate of potassa formed on allowing bromine water to act upon chlorate of potassa with the addition of a little nitric acid—an adjunct which, under parallel circumstances, promotes the formation of iodate of potassa. It seems, therefore, decided that the affinity between oxygen and bromine is less than that between oxygen and chlorine.

Contribution to the History of Sulpho-Urea.—M. Nencki.—If a cold saturated aqueous solution of sulpho-urea is mixed with a solution of cyanide of mercury in equivalent amount, a crystalline double salt is thrown down which, when washed and dried over sulphuric acid, yielded results agreeing with the formula—

This compound is sparingly soluble in cold water, and cannot be re-crystallised from hot water, since on heating the aqueous solution a black precipitate of sulphide of mercury is formed, and an odour of hydrocyanic acid is given off. If the solution is boiled till all sulphur is deposited the filtered liquid yields on evaporation crystals of dicyanamide. If sulpho-urea is gently heated with anhydrous acetic acid it dissolves and yields monoacetylic sulpho-urea in yellowish prisms, which can be obtained colourless by repeated crystallisation. Its composition is—

Carbon	30.50
Hydrogen	5.08
Nitrogen	23.72
Sulphur	27.11
Oxygen	13.56

99.97

agreeing with the formula $\text{C}_3\text{H}_6\text{N}_2\text{SO}$, or—

This substance is readily soluble in alcohol and hot water, sparingly in cold water and ether. It melts at 11.5° to a colourless liquid. The aqueous solution has a neutral reaction, and forms with the chloride of platinum a crystalline salt sparingly soluble in water—

If acetylic sulpho-urea is distilled with anhydrous phosphoric acid an oil of a pungent odour, heavier than water, distils over.

Determination of Chloral.—V. Meyer and H. Haffner.—The authors remark that chloral hydrate is often found very impure, whence a simple and accurate method for its quantitative examination becomes needful. With aqueous solutions of alkalis chloral hydrate is completely resolved into chloroform and alkaline formiate according to the equation, $\text{C}_2\text{Cl}_3\text{H}_5\text{O}_2 + \text{NaOH} = \text{CHCl}_3 + \text{HCO}_2\text{Na} + \text{H}_2\text{O}$. 1 equivalent of chloral hydrate neutralises 1 equivalent of soda, or 165.5 grms. of the former require 1000 c.c. of normal solution of soda. If, therefore, a weighed amount

of the sample under examination is mixed with a known excess of normal soda solution, and the remaining excess of soda is determined by titration with standard acid, the soda consumed and the corresponding amount of pure chloral hydrate are found by the equation—

$$x = \frac{(a-b) 165.5}{1000} \text{ grm.}$$

a denoting the number of c.c. of normal soda consumed, and b the c.c. of normal acid used for titration. If free hydrochloric acid is present as an impurity, it is neutralised by shaking up the aqueous solution with pure carbonate of lime, and expelling the free carbonic acid by prolonged agitation in the measuring cylinder.

Aromatic Phosphorus Compounds.—A. Michaelis. —Two of the aromatic phosphorus compounds, corresponding to those of nitrogen, are peculiarly interesting; phosphoraniline, $\text{PH}_2\text{C}_6\text{H}_5$, and $\text{PO}_2\text{C}_6\text{H}_5$, both of which had not been obtained. The author passed a mixture of the vapours of benzol and chloride of phosphorus through a glass tube filled with pieces of pumice, and heated nearly to redness. The distillate was returned, and again passed over until 1000 grms. of a liquid, boiling at temperatures higher than 80° was obtained. By fractional distillation a colourless liquid, $\text{PCl}_2\text{C}_6\text{H}_5$, was obtained, boiling at 222° . This substance—phosphophenyl-chloride—is a very permanent liquid, refracting light strongly, and fuming in the air with an intense odour resembling both phosphuretted hydrogen and hydrochloric acid. It affords the prospect of a new series of interesting aromatic derivatives.

Behaviour of Ozone with Water.—C. Rammelsberg. —Schöenbein, Marignac, and Andrews pronounce ozone insoluble in water; whilst Sorét, Meissner, and Houzeau maintain the opposite view. Carius proved that at low temperatures (0.5° to 5°) oxygen gas, rich in ozone, obtained by electrolysis, forms with water a liquid which gives the reactions of ozone. Engler and Nasse have also convinced themselves of the solubility of ozone. The author examines whether ozoniferous oxygen or air when passed at ordinary temperatures through water would give a liquid capable of producing the reactions of ozone. The result showed that when chlorine was absent the reaction with starch and iodide of potassium was obtained very slightly in one case only, and that with indigo and thallium salt not at all. The so-called "ozone water" of Krebs, Kroll, and Co. contains chlorine, and is pronounced by Dr. Jacobsen to be a dilute solution of hypochlorous acid.

Hydrates of Monobasic Acids.—A. Henninger.—A reply to Geuther's claim of priority for the theory of the hydrates of the fatty acids. He quotes the following formula which Geuther has given for acetic acid:—

Sequel to Investigations on some New Derivatives of Sulpho-Carbaminic Acid.—H. Hlasiwetz and J. Kachler.—The authors have found that, with the exception of the aniline derivative, their results had been anticipated by Zeise in 1842.

Remarks on Petersen's Essay "On the Constitution of the Benzols."—H. Salkowski.—A controversial-theoretical essay on the supposed position of the lateral groups in the derivatives of benzol.

Occurrence of Arabic Acid (Gum) in the Sugar Beet, and on Gum-Sugar.—H. Scheibler.—This paper is not suited for abstraction. We shall endeavour to give it in full.

Reimann's Färber Zeitung, No. 18, 1873.

This number consists chiefly of receipts for dyeing and printing upon woollen, cotton, silk, and mixed tissues.

Dyeing Straw Hats.—The articles are boiled in a mixture of 1 lb. sulphate of alumina, $\frac{1}{2}$ lb. prepared tartar, $\frac{1}{2}$ lb. sulphuric acid, to which orchil, extract of indigo, and turmeric are added as required.

Carminate of Lime.—The compound of carminic acid—the colouring principle of cochineal—with lime is, according to Guignet, distinguished by its black colour from the other cochineal lakes, which are mostly violet. There is consequently always a black precipitate formed when a decoction of cochineal comes in contact with a solution of lime, or even with calcareous water. Pure carminic acid does not, indeed, precipitate gypsiferous water. The reason why decoction of cochineal produces this effect is because it is slightly alkaline. The black carminate of lime can be produced by mixing bicarbonate of lime in solution with decoction of cochineal. The black precipitate is probably neutral carminate of lime, insoluble in water and alcohol. An excess of lime colours the precipitate a deep violet. Concentrated acetic acid dissolves the precipitate with a deep red colour.

No. 19.

The number commences with receipts for sizing linen, for producing ponceau and aniline blue on mohair yarns, superior black on cotton yarns, flamed effects on the same material, deep madder red on wool, naphthalin yellow on woollen yarn, reddish drabs on wool, iodine green on woollen yarn, light and dark maize flesh colour and mulberry on cotton, pensé, crimson, Bismarck, drab, and grey on jute.

Black Spots in Grain Dyeing.—Traces of iron should be carefully avoided in all operations with cochineal, as the compounds of this metal with carminic acid are black. Guignet's opinion that the black spots sometimes found on grain dyed goods are derived from carminate of lime is probably erroneous, as the flots in which these colours are dyed is so acid that any carminate of lime would be at once re-dissolved. Such spots the author considers due to iron present as an impurity in the tin mordants.

Birls in Woollen Tissues.—To remove birls Descoubet saturates the cloth with steam, and conducts it through a narrow slit into a chamber filled with hydrochloric acid gas. Here the cloth is passed several times up and down, and is then conducted into another chamber and dried at a somewhat elevated temperature. It is then run into an alkaline bath, which removes all traces of the acid that has destroyed the vegetable matter.

Aniline Red-Violet.—Hobrecker prepares a reddish aniline by treating rosaniline with iodide of methyl and chloride of benzyl, ($\text{C}_{14}\text{H}_7\text{Cl}$). The metallic green acicular crystals, insoluble in water and sparingly soluble in cold alcohol, are rosaniline, in which 3 atoms of hydrogen are replaced by benzyl, C_{14}H_7 , the whole being combined with 1 atom of iodomethyl.

Patent Mixture for Cleansing Carpets.—In noticing an English patent for cleansing carpets—which, by the way, prescribes $3\frac{1}{2}$ lbs. soda, and $4\frac{1}{2}$ ozs. washing crystals—the editor very properly remarks that a final treatment with dilute oxalic acid would improve the colours.

Impurities in Tin Crystals.—Bronner recommends dyers to prepare their own bichloride of tin from commercial tin crystals, which, he thinks, are rarely contaminated, except with sulphates of soda and magnesia—substances easily detected by means of chloride of barium. The editor points out that tin crystals are often adulterated with alkaline chlorides, forming double salts much less easily detected.

Preparation of Caustic Baryta.—M. Rosenthal's process is founded upon the decomposition of sulphide of barium dissolved in boiling water by oxide of zinc. Caustic baryta and sulphide of zinc are formed.—*Year-Book of Pharmacy*.

PATENTS.

ABRIDGMENTS OF PROVISIONAL AND COMPLETE SPECIFICATIONS.

Improvements in utilising waste products obtained in the manufacture of phosphorus, and in the manufacture of certain metallic compounds containing phosphorus. J. H. Player, manufacturer, Birmingham. November 22, 1872.—No. 3501. This invention consists in utilising the gaseous phosphorus compounds obtained in the manufacture of phosphorus by passing the said gaseous compounds through a solution of sulphate of copper; by this treatment phosphide of copper is obtained. The invention further consists in adding phosphorus to copper and alloys of copper for the purpose of giving tenacity and other valuable properties thereto by the use of phosphide of copper instead of uncombined phosphorus, as commonly practised.

Improvements in the mode of and apparatus for treating horny and other analogous animal substances for the purpose of converting them into an elastic substance to be used in place of whalebone, bristles, and for other purposes for which such elastic substance may be applicable. W. Birch, engineer, Penrose Street, Walworth Road, Surrey. November 22, 1872.—No. 3503. The treatment to which the horny substance is subjected (to effect the object of this invention) is a combination of a chemical and mechanical process. The chemical process, which consists in steeping the horny substance in an infusion of sage leaves or plants of that class, is used to soften the substance, and the subsequent mechanical operation is either to fatten, roll out, and extend or mould the softened horny matter, or to disintegrate it into thread.

Improvements in the filtration and purification of fluids, and in the manufacture of manure. David Curror, Wester Craigduckie, Fifeshire, and James Dewar, 15, Gilmore Place, Edinburgh. November 25, 1872.—No. 3529. The features of novelty which constitute this invention are—Soaking and applying peat (in its natural state, or after being dried or partially carbonised, and either by itself or mixed, or in connection with chalk, lime, sand, earth, or aluminous clay) as a filtering medium or as a discolourising, deodorising, defecating, disinfecting, or absorbing agent or material, that (1) colouring matters in suspension or solution are retained or absorbed, and the fouled water greatly discoloured, clarified, deodorised, defecated, and disinfected, and (2) that the peat (when the fluid passed through it has contained nitrogenous matters) is converted into a valuable manure. This is effected by artificial filtration, the filter bed being made up of ordinary filtering material with a layer or layers of peat of the required thickness laid on the surface of it.

Improvements in manuring, disinfecting, and deodorising. James Raymond Belford, Clifton, Gloucester. November 25, 1872.—No. 3533. This specification describes a manure, and disinfecting and deodorising compound, being a combination of the different salts of ammonia, potash, and soda, sulphates, phosphates, silicates, muriates, &c., in the several proportionate amounts required for the full development of all crops, together with a certain quantity of mineral acids and various phenyl compounds, sulphites, and other antiseptics.

A new or improved industrial manufacture of acetate of alumina, and the treatment of the resulting products. Farnham Maxwell Lyte, chemist, of the firm of Storck and Co., Asnières, France. (A communication from Henri Storck, Edouard Hentsch, Auguste Hentsch, André Lutscher, and Frederic Grininger, constituting the firm of Storck and Co., Asnières, France). November 26, 1872.—No. 3532. The feature of novelty of this invention refers to the manufacturing of acetate of alumina. In carrying out this invention I convert phosphate of alumina into acid phosphate by dissolving it into phosphoric acid. To the liquor I add some acetate of lead in proportionate quantity to that of phosphoric acid therein, that is to say, containing enough lead to precipitate the whole phosphoric acid. Soluble acetate of alumina and insoluble phosphate of lead are formed. I separate the acetate of alumina by filtration, which I treat afterwards similarly to that obtained by double decomposition with sulphate of alumina for industrial purposes. As to the phosphate of lead, I use it to produce pure phosphoric acid, decomposing it by sulphuric acid or sulphuretted hydrogen, or a phosphate is formed thereof in treating it by an alkaline sulphide, or it may be mixed with charcoal for producing phosphorus by distillation.

Improved process of treating and purifying crude phosphoric acid, and in the production of soluble phosphates, also for the manufacture of phosphorus, and the treatment of certain residues resulting therefrom, and phosphate of alumina. Farnham Maxwell Lyte, chemist, of the firm of Storck and Co., Asnières, France. (A communication from Henri Storck, Edouard Hentsch, Auguste Hentsch, André Lutscher, and Frederic Grininger, constituting the firm of Storck and Co., Asnières, France). November 28, 1872.—No. 3585. The features of novelty of this invention consist—First. In the production of sulphuric acid from phosphoric acid, and certain of its compounds by means of barium and its salts. Second. In the application of phosphoric acid (purified according to this invention) to the manufacture of phosphate of sodium, phosphate of ammonia, and other phosphates, and its employment, as well as the residues in manufactures. Third. In the manufacture of a paste wherewith to charge retorts in the manufacture of phosphorus; the paste is made by evaporating barytated phosphoric acid, and mixing therewith powdered phosphorite or bone-earth and charcoal, and subjected to distillation.

Improvements in the manufacture of sugar, and in apparatus to be used therefor. Alfred Vincent Newton, 66, Chancery Lane, Middlesex. (A communication from Santiago Dod, Havana, Cuba). November 28, 1872.—No. 3588. One part of this invention, which relates to the manufacture of sugar from either the sugar-cane or beet-root, consists in the generation of the steam used in sugar-works (including the supply of the clarifiers, also the working of the pump or pumps, and, if desired, the driving of the engine or engines employed) from the juice itself as a substitute for water, in or during the earliest stages of con-

centrating the juice, by boiling the latter under pressure in a close vessel or vessels exposed to the direct application of heat, whereby fuel and labour are largely economised. The invention also comprises improvements in the vacuum-pans and other parts of the apparatus employed in the manufacture of sugar.

Analysis of Food, Water, and Air.—Mr. WANKLYN has opened a Laboratory at 117, Charlotte Street, Fitzroy Square, and is prepared to give Practical Instruction in Chemical Analysis to Medical Officers of Health, and to persons proposing to undertake the duties of Public Analysts under the new Act.

North London School of Chemistry, Pharmacy, &c.—Conducted by Mr. J. C. BRAITHWAITE, for thirteen years Principal Instructor in the Laboratories of the Pharmaceutical Society of Great Britain, and Demonstrator of Practical Pharmacy, Pharmaceutical Latin, &c.

The Session 1872-1873 will commence on the 1st of October when—

The LABORATORY will be open at 10 a.m. for Instruction in Practical Chemistry as applied to Pharmacy, Medicine, Analysis, &c. Terms moderate.

The CLASSES will meet as usual.

The CHEMICAL and TOXICOLOGICAL CLASS on Monday and Thursday evenings at 8 p.m., commencing October 1st.

The LATIN CLASS on Tuesdays and Fridays at 8 p.m., commencing October 2nd.

The MATERIA MEDICA and BOTANICAL CLASS, every Wednesday and Saturday at 8 p.m., commencing October 3rd.

The BOTANICAL GARDEN affords to Students desirous of acquiring a *Practical Knowledge of Botany* every facility for doing so. During the Season BOTANICAL EXCURSIONS are made every Saturday at 10 a.m.

Fee to either of the above Classes Half-a-Guinea per Month. Pupils can enter at any period to either Classes or Laboratory.

All Fees must be paid in advance.

PRIVATE TUITION for the usual Examinations of the Society, the Modified Examination, &c.

Letters of inquiry should be accompanied with a stamped envelope.

Address—54, KENTISH TOWN ROAD, N.W.

Royal Polytechnic Institution, 309, Regent Street.—Laboratory (entirely re-fitted) and Class-Rooms are now open.

ASSAYS, ANALYSES and Investigations connected with PATENTS conducted.

Pupils received for Class and Private Study. Special facilities are offered to persons preparing for GOVERNMENT EXAMINATIONS.

Classes are now forming for Practical Study in CHEMISTRY, STEAM, and PHYSICS.

For particulars, apply to Professor E. V. GARDNER, F.A.S. M.S.A. at the Institution.

BERNERS COLLEGE of CHEMISTRY.—

EXPERIMENTAL MILITARY and NAVAL SCIENCES, under the direction of Professor E. V. GARDNER, F.E.S., &c., of the late Royal Polytechnic Institution and the Royal Naval College.

The Laboratory and Class Rooms are open from 11 to 5 a.m., and from 7 to 10 p.m. daily.

Special facilities for persons preparing for Government and other examinations.

Private Pupils will find every convenience.

Analyses, Assays, and Practical Investigations connected with Patents, &c., conducted.

For prospectus, &c., apply to Prof. E. V. G., 44, Berners-street, W.

THE LIVERPOOL COLLEGE OF CHEMISTRY, 96, DUKE STREET, LIVERPOOL.

Specially Devoted to the Study of CHEMISTRY, TECHNOLOGY and ASSAYING.

Laboratories open throughout the Year.

MARTIN MURPHY, F.C.S., &c., Principal (Successor to the late Dr. SHERIDAN MURPHY).

A Special Laboratory is devoted to Commercial Analyses of every description, and to Mineral Assays.

Manufacturers' and Smelters' Analyses and Assays undertaken on Contract.

Patentees and Inventors Advised and Assisted. Works and Mines Inspected. The Erection of Manufacturers' Plant Supervised, &c.

Terms and Fees VERY MODERATE.

Further Particulars and Full Prospectus on application to The Principal, MARTIN MURPHY, F.C.S. &c.

Water-glass, or Soluble Silicates of Soda and Potash, in large or small quantities, and either solid or in solution, at ROBERT RUMNEY'S Ardwick Chemical Works Manchester

INSULATED ELECTRICAL WIRES.**J. & W. RICKARD,****ASHBOURNE ROAD MILLS, DERBY,**

Manufacture all kinds of Silk and Cotton-Covered Copper Wires. Thorough Insulation. Conductivity 90 per cent guaranteed.

Price List on application.

GERMAN SILVER WIRES IN SILK OR COTTON COVERING TO ORDER.

**FOOT, BARRET, AND TEMPLE,
BATTERSEA.****ACETIC & NITRIC ACIDS.**MANUFACTURERS OF
HYDRATE OF CHLORAL.**OXIDE OF IRON.**

We are prepared to supply, on moderate terms,
HYDRATED PEROXIDE OF IRON (BOG OCHRE),
Same quality as supplied by us to several of the most extensive Gas
Companies, and which has given entire satisfaction.
FRANCIS RITCHIE AND SONS, BELFAST.

**BISULPHIDE OF
CARBON,
PROTOSULPHATE
RED OXIDE,
OXYCHLORIDE,**

Sulphocyanide,
And every other Mercurial Preparation.

BISULPHITE OF LIME, TETRACHLORIDE OF CARBON.

Oxysulphuret of Antimony, Glacial Acetic Acid,

**LIQUOR AMMONIÆ,
SULPHIDE OF IRON,
PURE ACIDS,
CHLORIDE OF SULPHUR,
ACETONE,
CHLOROFORM,
ALDEHYDE,
CHLORATE BARYTA,
ARSENIC ACIDS,
FRUIT ESSENCES FOR CON-
FECTIONERY & LIQUEURS,**

**PERCHLORIDE OF IRON,
SULPHITE AND HYPOSUL-
PHITE OF SODA,
PHOSPHATES OF SODA AND
AMMONIA,
ETHERS,
BROMIDES,
IODIDES,
SCALE AND GRANULAR PRE-
PARATIONS.**

ALSO,

Pure Photographic Chemicals of every kind.

MANUFACTURED BY

**WILLIAM BAILEY & SON,
HORSELEY FIELDS CHEMICAL WORKS,
WOLVERHAMPTON.**

ESTABLISHED 1798.

**ROBERT DAGLISH & CO.,
BOILER MAKERS, ENGINEERS, AND
MILL-WRIGHTS,
BRASS AND IRONFOUNDERS,
ST. HELEN'S FOUNDRY, LANCASHIRE.**

Makers of every description of Chemical, Colliery, Copper Ore, Gold
Mining, and Glass Machinery, including Crown, German Sheet, and
Plate Glass Plant, as supplied to some of the largest Firms in England,
Ireland, Scotland, and Wales.

Makers of the latest Improved Revolving Black Ash Furnace,
with Siemens's Patent Gas Arrangement, and as used in the Manufac-
ture of Soda.

Improved Valveless Air Engines, and Pumps for Acid Forcing, Air
Agitators, Compressors for Collieries, and Weldon's Patent Chlorine
Process.

Caustic, Chlorate, Decomposing, and Oxalic Pans.

Gas Producers for Heating Furnaces.

Pyrites Burners for Irish, Norwegian, and Spanish Ores.

Retorts, Acid, Gas, Nitre, Nitric Acid, and Vitriol Refining.

Improved Steam Superheaters for Resin Refining, &c.

Improved Steam Sulphur Pans.

Photographs, and other information, supplied on receipt
of Orders.

Chloride of Calcium (Purified Muriate of Lime),
total insoluble impurities under $\frac{1}{2}$ per cent.

CHLORIDE OF BARIUM (Muriate of Baryta), free from Iron
and Lead, total impurities, water excepted, under $\frac{1}{2}$ per cent

GASKELL, DEACON, & CO.,

ALKALI MANUFACTURERS WIDNES, LANCASHIRE.

Silicates of Soda and Potash in the state of
Soluble glass, or in **CONCENTRATED SOLUTION** of first
quality, suited for the manufacture of Soap and other purposes,
supplied on best terms by **W. GOSSAGE and Sons, Widnes**
Soapery, Warrington.

London Agents, **CLARKE and COSTE**, 19 and 20, Water Lane,
Tower Street, E.C., who hold stock ready for delivery.

LIEBIG COMPANY'S EXTRACT OF MEAT.
—None genuine without the Inventor's facsimile in blue being
on the Trade-mark label and outer cover. Pure condensed Essence of
Beef Tea, excellent economic flavouring stock for soups, sauces, and
made dishes.

"Food for the nerves." (Liebig).

SCIENTIFIC PRESENTS.—Collections to
Illustrate "Lyell's Elements of Geology," and facilitate the
important study of Mineralogy and Geology, can be had at 2s. 5s. 10s. 20s.
50s. to 500 guineas; also single specimens of Minerals, Rocks, Fossils,
and Recent Shells. Geological Maps, Hammers, all the recent pub-
lications, &c., of **J. TENNANT, Mineralogist to Her Majesty**, 143,
Strand.—Private Instruction is given in Geology and Mineralogy by
Mr. Tennant, F.R.G.S., at his residence, 149, Strand, W.C.

PRACTICAL CHEMISTRY.

Laboratory, 60, Gower Street, Bedford Square, W.C.

Mr. Henry Matthews, F.C.S., is prepared
to give instruction in all branches of **PRACTICAL**
CHEMISTRY, particularly in its application to **MEDICINE,**
AGRICULTURE, and COMMERCE.

The Laboratory is open daily, except Saturday, from ten to five
o'clock; on Saturday, from ten till one o'clock.
Mr. Matthews is also prepared to undertake **ANALYSES** of every
description.

For Particulars and Prospectuses, apply to **Mr. Henry Matthews**
the Laboratory, 60, Gower Street, Bedford Square, W.C.

ST. HELEN'S FOUNDRY, LANCASHIRE.**

Makers of every description of Chemical, Colliery, Copper Ore, Gold Mining, and Glass Machinery, including Crown, German Sheet, and Plate Glass Plant, as supplied to some of the largest Firms in England, Ireland, Scotland, and Wales.

Makers of the latest Improved Revolving Black Ash Furnace, with Siemens's Patent Gas Arrangement, and as used in the Manufacture of Soda.

Improved Valveless Air Engines, and Pumps for Acid Forcing, Air Agitators, Compressors for Collieries, and Weldon's Patent Chlorine Process.

Caustic, Chlorate, Decomposing, and Oxalic Pans.

Gas Producers for Heating Furnaces.

Pyrates Burners for Irish, Norwegian, and Spanish Ores.

Retorts, Acid, Gas, Nitre, Nitric Acid, and Vitriol Refining.

Improved Steam Superheaters for Resin Refining, &c.

Improved Steam Sulphur Pans.

Photographs, and other information, supplied on receipt of Orders.

Chloride of Calcium (Purified Muriate of Lime),
total insoluble impurities under $\frac{1}{4}$ per cent.

CHLORIDE OF BARIUM (Muriate of Baryta), free from Iron and Lead, total impurities, water excepted, under $\frac{1}{4}$ per cent

GASKELL, DEACON, & CO.,

ALKALI MANUFACTURERS WIDNES, LANCASHIRE.

Silicates of Soda and Potash in the state of
Soluble glass, or in CONCENTRATED SOLUTION of first quality, suited for the manufacture of Soap and other purposes, supplied on best terms by W. GOSSAGE and Sons, Widnes Soapery, Warrington.

London Agents, CLARKE and COSTE, 19 and 20, Water Lane, Tower Street, E.C., who hold stock ready for delivery.

SCIENTIFIC PRESENTS.—Collections to illustrate "Lyell's Elements of Geology," and facilitate the important study of Mineralogy and Geology, can be had at 2, 5, 10, 20, 50, to 500 guineas; also single specimens of Minerals, Rocks, Fossils, and Recent Shells. Geological Maps, Hammers, all the recent publications, &c., of J. TENNANT, Mineralogist to Her Majesty, 149, Strand.—Private Instruction is given in Geology and Mineralogy by Mr. Tennant, F.R.G.S., at his residence, 149, Strand, W.C.

PRACTICAL CHEMISTRY.

Laboratory, 60, Gower Street, Bedford Square, W.C.

Mr. Henry Matthews, F.C.S., is prepared to give instruction in all branches of PRACTICAL CHEMISTRY, particularly in its application to MEDICINE, AGRICULTURE, and COMMERCE.

The Laboratory is open daily, except Saturday, from ten to five o'clock; on Saturday, from ten till one o'clock.

Mr. Matthews is also prepared to undertake ANALYSES of every description.

For Particulars and Prospectuses, apply to Mr. Henry Matthews the Laboratory, 60, Gower Street, Bedford Square, W.C.

Methylated Spirits.—David Smith Kidd, Licensed Maker, Commercial Street, Shoreditch, N.E. Also FINISH, FUSEL OIL, and RECT. NAPHTHA.

VOLUME XXVIII.

EDITED BY WILLIAM CROOKES, F.R.S., &c.

No. 710.—FRIDAY, JULY 4, 1873.

ON BUTTER.*

By J. CAMPBELL BROWN, D.Sc. (Lond.), F.C.S.,
Lecturer on Chemistry and Toxicology at the Liverpool School of
Medicine, Public Analyst for Liverpool, Cheshire, and the Isle of Man.

Definition of Butter.—Pure butter is a fat which has passed through the udder of the cow or other animal as one of the constituents of milk, and which has not been decomposed, by keeping or otherwise, into fatty acids and glycerin.

In milk and cream, the fat is all contained in minute round globules, and butter appears, under the microscope, full of these globules. Chemically, it consists of a mixture of neutral fats, the glycerides of the non-volatile acids, palmitic acid, ($C_{16}H_{32}O_2$), and butyroleic acid ($C_{12}H_{24}O_2$); and the glycerides of the volatile acids, butyric acid ($C_4H_8O_2$), capronic acid ($C_6H_{12}O_2$), caprylic acid ($C_8H_{16}O_2$), and caprinic acid ($C_{10}H_{20}O_2$). (Wagner and Crookes). The last four glycerides are the characteristic fats of butter.

When butter has been decomposed, the rancid taste and smell make its condition evident to every one. The skill of the analyst is most frequently directed to the detection of fats from the flesh of animals or from the vegetable kingdom. The fats which are generally used as adulterants or as substitutes for butter are suet, tallow, dripping, lard, a mixture of refined fats sold under various names, palm and similar vegetable oils. The most characteristic ingredients in these fats are stearin, margarin, and palmitin.

Stearin is a crystalline fat, melting at $144^\circ F.$, and solidifying at $124^\circ F.$, soluble in hot ether, or in seven times its weight of boiling alcohol, but deposited from both these solutions on cooling.

Margarin forms scales, which melt at about $116^\circ F.$, and are soluble in warm ether.

Palmitin is a solid crystalline fat, melting at from 113° to 143° , and solidifying at 114° . It is readily soluble in ether, sparingly soluble in alcohol. Stearin, margarin, and palmitin are seldom obtained pure; they occur in Nature dissolved in olein and other oils, which lower the melting-point. For instance, mutton and beef suet, lard, and palm oil melt at temperatures from 25° to 55° below the melting-points of stearin and palmitin.

In drawing up the following table for the examination of butter, I have made free use of the observations of Dr. Ballard (CHEMICAL NEWS, vols. iv. and v.), and the scheme of Dr. Parkes ("Hygiene," chap. v., section xi.); but I depend chiefly on my own observations on a large number of samples from different sources, made during the years 1871 and 1872.

* From the "Liverpool and Manchester Medical and Surgical Reports, 1873." Communicated by the Author.

Table for the Examination of Butter.

1. Weigh out an ounce of the sample of butter which is to be examined, place it in a test-tube seven-eighths of an inch in diameter, and melt by placing the tube in hot water. Place a thermometer, with a pear-shaped bulb, so that the bulb shall be in the middle of the fat about 1 inch below the surface, and allow the whole to cool spontaneously. If the quantity of water in the butter be large, it will collect in the tube below the fat; the casein will also collect in the lower part of the tube. Watch the mass as it cools, and note when solidification commences and when it is complete. The following are the average solidification-points:—

With pure butter the thermometer is obscured between 74° and 68° , and the mass is solid at 60° .

Beef dripping obscures the thermometer at 79° , and is solid at 72° .

Mutton dripping obscures the thermometer at about 85° , and is solid at 84° .

Lard obscures the thermometer at 84° , and is solid at from 79° to 70° , but it often remains as soft as butter at a much lower temperature.

Mixtures solidify at intermediate temperatures.

2. Determine the quality of the butter by the taste and smell of the re-congealed fat and of the original sample.

3. Examine several portions of the original sample by means of a good microscope, using a $\frac{1}{4}$ -inch or $\frac{1}{2}$ -inch object-glass. In butter made from milk or cream, nothing is seen except the characteristic globules, and the granular masses of curd, and the cubical crystals of salt. The hard fats of butter are present in the globules in a state of solution, and are not recognisable in a separate form.

If stearic acid, stearin, or palmitin be present in separate form, they will be recognised by single fusiform crystals, or star-like aggregations of acicular crystals. They indicate the presence of melted fats.

Other substances, such as starch, flour, palm oil corpuscles, Irish moss, colouring matter, &c., may also be distinguished by the microscope, as distinct from butter or fats.

4. Examine the same portions with the same object-glass, together with a polariscope, consisting of two Nicol's prisms and a selenite plate. The crystals referred to in (3) polarise light, and when viewed by the polariscope are more distinctly defined. Particles of suet and other fats, which have not been melted, may also be distinguished by their action on polarised light, by their amorphous form, and by their membranes.

5. Repeat the microscopic examination after the addition of tincture of iodine, acetic acid, and other reagents usually employed to detect substances other than fat.

6. Weigh carefully a convenient quantity of the sample, say 1 oz., in a tared porcelain dish, evaporate in a water-bath, or in air-bath, at 212° , until free from water, and

weigh again; the difference is the amount of water per ounce, which should not exceed 35 grs. (5 to 10 per cent; Parkes).

7. Dissolve the residue in ether, warming gently until the whole of the fat is dissolved, filter through a weighed filter-paper, collecting the filtrate in a beaker, then wash the dish and filter-paper with ether until a total of 5 or 6 ozs. has been used, and allow the whole to stand for some time at a temperature of 65°.

8. Dry the precipitate on the filter-paper, and weigh; deduct the weight of filter-paper; the remainder is approximately the amount of curd, or casein, and salt.

9. Wash the precipitate with boiling water, dry at 212°, and weigh; deduct the weight of filter-paper; the remainder is the amount of curd or casein, which, in good butter, should not exceed 15 grs. per oz. (3 to 5 per cent; Parkes).

10. Estimate the salt, by means of nitrate of silver, in the aqueous washings from (9), or wash another weighed portion of butter thoroughly with distilled water, and determine the salt by nitrate of silver. It should not amount to more than 8 grs. per oz. in fresh butter (0.5 to 2 per cent; Parkes), or 35 grs. per oz. in salt butter (8 per cent; Parkes).

11. If the ethereal solution of the fat from (7) has formed a deposit at 65°, decant and filter off the clear solution, and examine the deposit, which is probably stearin, according to (12).

Evaporate the ethereal solution down to 4 ozs., and allow it to stand for several hours at 65°. Filter off the deposit, which probably still contains stearin, and examine it also according to (12).

Allow the ethereal solution to evaporate down to 3 ozs., and allow it to stand for some time at 65°. Filter off the deposit, which may still contain some stearin mixed with palmitin, and examine it separately, according to (12). If the butter is adulterated, some of the stearin, and much of the palmitin, will still remain in solution, and may be obtained by continuing the process of spontaneous evaporation.

Some samples of pure butter yield no deposit from 3 ozs. of ether at 65°; but fairly good butter will generally form a slight deposit, the amount of which varies in different samples. A sample of butter known to be pure should be examined side by side with the sample suspected to be adulterated; and, as winter butter is a more solid fat than summer butter, the former should be chosen for the comparative experiment.

12. (a). Place each of the above-mentioned deposits in a thin weighed glass tube, and, after evaporating off the ether, weigh the fat, and determine its melting-point; melt carefully, and allow it to cool gradually. Place a small accurately graduated thermometer with pear-shaped bulb in the melted fat, and observe the temperature at which the latter begins to solidify. When quite solid, re-warm the tube gradually, by placing it in water, the temperature of which is slowly raised, and observe the re-melting-point of the fat.

(b). Or, melt the fats in a thin glass or porcelain dish, floated in water, the temperature of which is slowly raised, a thermometer being placed in the water. In this case the apparent melting-point will be 2 or 3° above the correct figure, but the relative differences between the melting-points of the several deposits will be the same as in (12a).

13. Determine the taste and smell of each of the deposits.

14. The number of grs. per oz. may be reduced to parts per cent by multiplying by the factor 0.22857.

University of London.—The following is a list of the candidates who have passed the recent D.Sc. examination:—Branch VI., Electricity—Richard Wormell, M.A., University College and private study. Branch XIV., Geology—Augustus Constable Maybury, Royal School of Mines and University College.

(Concluded from p. 280.)

V. Attempts to Prepare Orthosulphobenzoic Acid.

THE fact that in the crude sulphotoluenic acid, employed in the preparation of parasulphobenzoic acid as above described, two varieties are contained, viz., the ortho- and para-; and, further, the fact that the crude product of the oxidation, in the form of the potassium salts, when fused with potassium hydroxide, yielded, as we have seen, salicylic as well as paraoxybenzoic acid, showed plainly that the ortho-acid had not been destroyed by the oxidising agent. The process was in other cases continued for a long time, and a large excess of the oxidising mixture employed; and still salicylic acid was obtained, its quantity, as compared with that of paraoxybenzoic acid, appearing rather to be increased than diminished under these circumstances.

This result was not what might have been anticipated after Fittig had called attention to the fact that ortho-compounds conduct themselves toward oxidising agents differently from the compounds of the two other series, the former being, as he states, completely destroyed, yielding carbonic acid and water. In the case under consideration two explanations might be given: either the orthosulphotoluenic acid had been converted into orthosulphobenzoic acid, or it had withstood the action of the oxidising mixture; for orthosulphotoluenic acid itself, when fused with potassium hydroxide, yields salicylic acid, if the heating be continued long enough, as was shown by Wolkow (*loc. cit.*).

The solution which yielded the acid barium parasulphobenzoate was evaporated down gradually, and, after it was reduced to a small volume, it was still found to contain a considerable quantity of an easily soluble salt, differing entirely from the difficultly soluble parasulphobenzoate. This was re-crystallised a number of times, and finally obtained in the form of microscopic needles; though even after repeated re-crystallisations its appearance hardly warranted the conclusion that it was a pure compound. It was, as stated, easily soluble in water; and the difference between its solubility in cold water and that in hot was not very great; so that the crystallisation was necessarily brought about by allowing the solution to stand for a length of time over sulphuric acid. The salt thus prepared was analysed after being thoroughly dried over sulphuric acid.

0.4215 grm. of the salt, on being heated to 240°, lost 0.0155 grm. H₂O, and then gave 0.2228 grm. BaSO₄ = 0.121 Ba.

	Calculated.		Found.

Though the results of this analysis agree but poorly with the calculated percentages, it nevertheless makes it appear exceedingly probable that this easily soluble substance is nothing but the salt of orthosulphotoluenic acid. Acid barium sulphobenzoate requires much less barium (23.10 per cent) and much more water (3 mol. = 9.11 per cent). The fact that more barium was found than is required by the theory would appear to indicate that the salt was rendered impure by the presence of a small amount of a neutral barium salt of sulphobenzoic acid. As the neutral barium salt of parasulphobenzoic acid corresponds in its properties very nearly to the salt here described, this becomes still more probable. Be this as it may, it is evident that the CH₃ group of orthosulphotoluenic acid has not been acted upon by the oxidising

mixture, nor has the acid been destroyed. The same results were obtained when a large excess of sulphuric acid and potassium bichromate were allowed to act upon the mixture of the two sulphotoluenic acids for a long time; so that the statement of Fittig, that the ortho-compounds are destroyed by oxidising agents, requires qualification. It seems, indeed, from this and a subsequent experiment, that the ortho-acid is acted upon with much less energy than the para-acid, if acted upon at all. This case agrees, however, with those mentioned by Fittig, in the fact that the toluen derivative yields no corresponding derivative of benzoic acid.

The destruction of aromatic compounds is by no means confined to those which belong to the ortho-series. The case of salicylic acid mentioned by Fittig is, indeed, no proof of his general statement, inasmuch as all aromatic oxyacids, as far as I have subjected them to experiment, are destroyed with equal facility. I have, for instance, treated salicylic, oxybenzoic, paraoxybenzoic, protocatechic, and gallic acids with sulphuric acid and potassium bichromate, and in each case exactly the same phenomena were observed. Gentle heating was sufficient to commence the process, which then proceeded violently to the end, accompanied by an evolution of carbonic acid, without the further aid of heat. On now examining the mixture, not a trace of a solid product could in any way be discovered. So that salicylic acid does not differ in this respect from other aromatic acids containing OH; and its conduct toward oxidising agents is, of course, no proof that it belongs to the ortho-series. This does not, however, detract from the value of Fittig's exceedingly interesting observation; it merely serves to define it more accurately.

That the ortho-compound, in the special case under consideration, is acted upon less energetically than the para-compound, was also shown in a rough way by the following experiment:—The potassium salts of the two sulphotoluenic acids were separated very nearly by means of crystallisation. The pure para-salt was introduced into the oxidising mixture, and the reaction that ensued carefully observed. The same quantity of ortho-salt, still containing some of the para-salt, was afterward introduced into the same quantity of the oxidising mixture as was employed in the former case, and the reaction compared with the former one. A striking difference was observed. Whereas the reaction commenced very quickly with the para-salt, and a strong evolution of gas took place; with the ortho-salt, it was necessary to apply heat for a longer time before the reaction fairly began, and then the process was markedly more sluggish, a very slow evolution of gas continuing for a long time. By means of approximate quantitative experiments, further, it was shown that the longer heat was applied to the vessel in which the oxidising process was going on, the smaller was the yield of para-acid; but in no case did I succeed in completely destroying either the ortho- or para-acid. This shows that the para-acid is very susceptible to the action of the oxidising agent, the oxidation taking place apparently at first in the methyl group, and then extending gradually to the whole molecule; whereas the ortho-acid resists the same influence strongly, and if oxidation takes place at all, it breaks up the compound, yielding the last products of combustion. Whether the same is true of other cases I am unable to say; facts do not speak against it at present, and further experiment can alone decide this point, which certainly possesses more than ordinary interest.

I was thus forced to abandon the hope of obtaining orthosulphobenzoic acid by the oxidation of orthosulphotoluenic acid by means of sulphuric acid and potassium bichromate. It is possible that other oxidising agents, as, for instance, potassium hypermanganate, may yield more satisfactory results. A preliminary experiment made with this salt in an alkaline solution showed that oxidation took place readily; and I shall soon commence the study of this reaction in detail.

VI. Oxidation of the Amides of Sulphotoluenic Acid.

The difficulty with which ortho-compounds are obtained, and the importance of studying them in a pure condition, in order to complete our knowledge of their conduct under various conditions, led me to undertake one more experiment, with the hope of finding a method for the preparation of orthosulphobenzoic acid. The experiment failed to bring about the desired object, but at the same time gave other interesting results, an account of which follows.

According to A. Wolkow (*loc. cit.*), the amides of the two sulphotoluenic acids can be separated from each other by means of crystallisation. This statement offered a prospect of obtaining an ortho-compound in pure condition; and I hence prepared a quantity of the amides from the crude mixture of potassium salts of sulphotoluenic acids. The perfect separation of the two by means of crystallisation is an exceedingly tedious operation, whether water or alcohol be employed as the solvent. From water the paramide crystallises first, and can then easily be purified; from the mother-liquor a mixture of the two amides is deposited. This fuses at 124°, and can only be resolved into its constituents by a very long series of recrystallisations. I succeeded at last in obtaining a small quantity of the ortho-amide in a pure condition, with all the properties as given by Wolkow.

Now, as the amide contains the group SO_2NH_2 instead of the sulpho-acid group SO_2OH , it seemed possible that its conduct toward oxidising agents might differ from that of the sulpho-acids. No attempts had as yet been made to oxidise compounds containing such a complicated group as SO_2NH_2 , and I was obliged to gain a certain amount of preliminary knowledge before proceeding to subject the ortho-amide to oxidation. For this purpose I introduced a few grammes of parasulphotoluen-amide into a noted amount of the oxidising mixture (sulphuric acid and potassium bichromate); and heated the whole gently for a short time. Soon the oxidation began, as was shown by a change in colour and an evolution of gas. The amide dissolved rapidly, and, soon after it had completely disappeared, a beautifully crystallised product began to make its appearance, and increased constantly in quantity. After cooling, the liquid was filtered off. The solid product remained on the filter, after being washed out with cold water, in a pure white condition. It consisted of beautiful, short, lustrous prisms that bore no resemblance to the original amide. It was found to be easily soluble in alkaline carbonates, carbonic anhydride being evolved, and was re-precipitated from these solutions in crystalline form on the addition of mineral acids. It was almost insoluble in cold water, and difficultly soluble in hot water; and, when only once crystallised from water, it had the form of flattened prisms, sometimes more than an inch in length. These had a high lustre, and while in the solution exhibited a very beautiful fluorescence. It was found to fuse at a very high temperature, but to undergo decomposition before this point was reached. These properties distinguish the new substance from the amide of parasulphotoluenic acid. Its composition was determined by the analysis.

- (1). 0.8657 grm. of the substance, thoroughly dried over sulphuric acid, were oxidised in a silver basin with saltpetre and potassium hydroxide (Liebig's method). There were obtained 1.03 grms. $\text{BaSO}_4 = 0.14146$ grm. S.
- (2). 0.5505 grm. of the dried substance were heated with soda-lime, and the vapours collected in dilute hydrochloric acid. In this way were obtained 0.262 grm. Pt; corresponding to 0.037163 N.

	Calculated.		Found.
$\text{C}_7\text{H}_7\text{O}_4$	155	77.11	—
S	32	15.92	16.34
N	14	6.97	6.75
	201	100.00	

These results agree with the formula—

and this formula agrees with the method of formation of the substance. We have—

I have given the acid the name *parasulphaminbenzoic acid*, as indicating the constitution which it undoubtedly possesses.

A compound of a similar constitution, but belonging to another series, is already known, viz., the so-called *sulphobenzamic acid*. This was prepared by Limpricht and Uslar*, and by Engelhardt†. The former obtained it by heating sulphobenzamide—

or ammonium ethylsulphobenzoate, with potassium hydroxide; further, by treating the compound $\text{C}_7\text{H}_6\text{N}_2\text{SO}_2$ (obtained from sulphobenzamide by treating with phosphorus chloride) with caustic potassa. In both cases ammonia is eliminated. Engelhardt obtained it by means of a complicated reaction, viz., the action of sulphur anhydride on benzonitrile, other products being formed at the same time. Sulphobenzamic acid being derived thus from ordinary (meta) sulphobenzoic acid retains, in all probability, the meta-position of the substituting groups; and, although it is not proved by experiment, it is probable that the amide group is in this case also situated in the sulpho group, and not in the carboxyl. The name would indicate the contrary; but the analogy that this compound shows with parasulphaminbenzoic acid, in which the amide group is undoubtedly situated in the sulpho group, leads me to believe that the name is incorrect, and that the name *metasulphaminbenzoic acid* would be more in accordance with the internal character.

To the account given above of the method of preparation and the properties of parasulphaminbenzoic acid, I need only add a few details. For the oxidation the following proportions were found to be most favourable:—To 20 grms. of potassium bichromate are taken 30 grms. of ordinary sulphuric acid, diluted with three times its volume of water; this mixture sufficed for the oxidation of 7 grms. of the pure amide. The amide is introduced into the mixture after the latter has become cool. At first the flask is heated by means of a very small gas-flame. A moderately violent action takes place, and in a short time the amide is entirely dissolved; now in a few minutes the separation of the oxidation product begins. The mass increases constantly in quantity until the liquid has the form of a thick paste. In about an hour from the beginning of the process the oxidation is completed. The whole is now allowed to cool down to the ordinary temperature, the product is filtered off and washed out with cold water, until the wash-water passes through colourless. On the filter is the parasulphaminbenzoic acid in the form of beautiful crystals, which only require to be re-crystallised from water once in order to be made perfectly pure. It is easily soluble in alcohol, and crystallises from this solvent in smaller crystals than are obtained from water; and these do not exhibit the property of fluorescence. It is precipitated in crystals, both from a hot and cold alcoholic solution, by water.

Sulphobenzamic acid crystallises, according to Limpricht and Uslar, in scales like potassium chlorate; according to Engelhardt, in rhombohedral crystals or in

needles consisting of aggregates of small rhombohedrons. Heated above the melting-point, it volatilises in white vapours. Distilled with phosphorus pentachloride, it yields a number of products, among which is metachlorbenzoyl chloride. It may be expected that parasulphaminbenzoic acid will under the same treatment yield parachlorbenzoyl chloride, a point which I shall decide by experiment.

Ethyl-parasulphaminbenzoate—

This beautiful compound is the most characteristic derivative of the acid. It is prepared in the usual manner by conducting dried hydrochloric acid gas into a solution of the acid in absolute alcohol, and afterward heating gently on a water-bath. Water gives no precipitate in the solution thus obtained. The alcoholic solution must be evaporated down to the consistence of syrup; it then congeals on cooling, and consists of a mass of fine, colourless needles. In water it is less soluble than in alcohol; in cold water much less than in hot. When boiled with water, it melts in the liquid before dissolving. From the aqueous solution it separates in the form of long, beautiful needles of a silken lustre. These arrange themselves nearly parallel, and may attain the length of several inches. In connection with the melting-point, this substance exhibits interesting though perplexing phenomena. In order to be sure that it was absolutely pure, I subjected it to re-crystallisation a number of times; though each time it was obtained in the same form, and possessed in the highest degree the appearance of a chemically pure substance. On endeavouring to determine the melting-point, however, I was surprised to find that this varied according to circumstances. When first heated, it melted entirely at 110° to 111° ; if it were now removed from the bath, and allowed to solidify, it melted immediately after at 94° to 95° ; the longer it was allowed to stand after the first melting, the higher the melting-point became, until finally, in about two hours, it again reached 110° to 111° . Specimens examined at different intervals showed melting-points which varied between the limits mentioned; every time that the substance was melted once and then allowed to congeal, and again immediately examined, the melting-point was found to be 94° to 95° . This, taken together with the fact that the substance was pure, is certainly very remarkable. It is possible that this case belongs in the same category with that observed by Zincke* in connection with the two modifications of benzophenon, which is in its turn decidedly inexplicable.

Of the ether, a sulphur estimation was made as follows:—

0.2849 grm. of the substance, dried over sulphuric acid, were oxidised with KOH and NO_3K (Liebig's method), and gave 0.2903 grm. $\text{BaSO}_4 = 0.03987\text{ S}$.

	Calculated.	Found.
$\text{C}_8\text{H}_{11}\text{O}_4\text{N}$	197 86.03	—
S	32 13.97	13.99
	229 100.00	

Ethyl sulphobenzamate also crystallises, according to the description, in "splendid, shining needles;" these were determined to be monoclinic prisms. No determination of the melting-point appears to have been made. "It dissolves easily in warm alcohol; somewhat less easily in boiling water."

Barium parasulphaminbenzoate, $(\text{C}_7\text{H}_5\text{SO}_4)_2\text{Ba} + \text{H}_2\text{O}$. This salt is prepared by boiling the acid with barium carbonate. It is easily soluble in cold and hot water, and crystallises in nodular aggregations.

The analysis gave the following results:—

0.497 grm. salt, dried over sulphuric acid, lost, at 200° , 0.0161 grm. H_2O ; and gave 0.2094 grm. $\text{BaSO}_4 = 0.12313\text{ grm. Ba}$.

H ₂ O	18	3.24	3.24
	555	100.00	

The corresponding salt of sulphobenzamic acid crystallises with 4H₂O as "a soft, wavelite, crystalline mass;" it gives off its water at 110°.

Ammonium parasulphaminbenzoate—

prepared by dissolving the acid in ammonia, is easily soluble in cold and hot water. It easily forms supersaturated solutions, which congeal on being disturbed. It crystallises in beautiful needles or long laminæ.

The ammonium salt of sulphobenzamic acid crystallises in laminæ.

The new acid is thus sufficiently well characterised as a chemical individual by these experiments; but, as it represents a class of derivatives differing from others in their more complicated nature, it deserves a more thorough examination. It is susceptible to the action of ordinary reagents, and yields compounds with them. It can be boiled with concentrated nitric acid without undergoing change, it being thrown down in crystalline form on the addition of water. It is insoluble in fuming nitric acid at the ordinary temperature; but dissolves when heat is applied. On the addition of water to the solution no precipitate is formed; on evaporating, however, a very easily soluble, colourless, crystalline product was obtained. Fuming sulphuric acid also dissolves it with the aid of heat, and as water gives no precipitate with the solution, it is probable that a sulpho-acid is formed; though in this connection it should be remembered that the isomeric body, sulphobenzamic acid, appears to yield sulphobenzoic acid when treated with sulphuric anhydride (Limpricht and Uslar). The study of these reactions I shall take up in due time. Parasulphaminbenzoic acid having a symmetrical structure, the investigation of its sulpho acid offers a possibility of throwing light upon the constitution of the tribasic acids of benzyl; the conversion of the two sulpho groups into carboxyl may succeed, though, after the experience of Ascher* with sulphoterephthalic acid, this is hardly probable.

I have already stated that the object of undertaking the oxidation of the amides of sulphotoluenic acids was to open another road with the hope of arriving in the end at a method for the preparation of orthosulphobenzoic acid; I also stated that this object was not attained. Orthosulphotoluenamide still containing some of the paramide was subjected to oxidation. It was immediately noticed that, as in connection with the sulpho acids, the action in this case was not as violent as in the case of the para compound. After heating for some time the product was examined. The parasulphaminbenzoic acid formed was filtered off, and the filtrate extracted with ether. The ethereal extract, on being distilled, left behind a residue consisting of orthosulphotoluenamide with a very little parasulphaminbenzoic acid. The latter can be readily removed by re-dissolving the whole in water, adding a little alkali to the solution, and then again extracting with ether. In this way absolutely pure ortho-amide can be obtained. This was again subjected to oxidation, and, after treating for a length of time, no new product could be discovered in the liquid—a portion of the substance only having been destroyed. Thus we see that the conduct of the ortho-amide is exactly analogous to that of the corresponding sulpho acid; and this serves to strengthen the conclusion drawn in regard to the conduct of ortho compounds in general toward oxidising agents.

The points which have been left unsettled thus far in this investigation will be considered in a second paper on a basis of experiments.—*Am. Journ. Sci.*

ON THE ENERGIES OF THE IMPONDERABLES, WITH ESPECIAL REFERENCE TO THE MEASUREMENT AND UTILISATION OF THEM.*

By the Rev. ARTHUR RIGG, M.A.

LECTURE I.

Introduction—Inter-Relations—Units of Measurement, &c.

"Imponderables," as a technical term, was in the last century a name given to those fluids which were supposed to convey electricity, light, heat, &c.; and, because these fluids could not be isolated and weighed, all that men received through their agency were also named "imponderables." These phenomena are now regarded as being due to motions in ponderable matter, and they are considered rather as forces causing motion in this matter, than either as fluids, or as that which can be conveyed, *i.e.*, carried, by fluids. The term is, however, retained as a brief mode of expressing the subject of this course of lectures, especially as no one can confidently assert that it may not again be reinstated in the position it once occupied.

The "energies of the imponderables," then, is a phrase comprehending all results of those unseen, unknown, and, by man, unweighable powers which pervade space. By such powers, the very sun and planets and stars are so influenced that they move in harmonious union or oneness, and, therefore, the name universe is applicable. With this extensive view of the influences and actions of the imponderables, these lectures are not to be concerned. The bounds of them are, however, easily defined. This earth, and that which man can utilise upon it, are our limits. Even when thus "cabined, cribbed, confined" to the earth and the handiwork of men, still those who have perused and thought over the title, *viz.*, "The Energies of the Imponderables, with especial reference to the Measurement and Utilisation of them," may have commented upon it in spirit, saying, "Fools rush in where angels fear to tread." When body, form, and fashion were first given to the scheme of this course, that great was the presumption, and that great, therefore, would be the failure, were not unknown feelings.

The causes of such views are simple and easily made clear. The energies of the imponderables have, in one form or another, occupied the attention of the most thoughtful, as well as the most practical, men in every age. They may not have given this name to the subject of their investigation, but, call it what you will, the ultimate source of all power that Nature gives to man is to be found in the energy of one or more of those unknown agents to which the name of imponderables has been given. To dwell upon this now would be to anticipate the series of lectures. It may suffice to state that the object of the course is to bring before you illustrations of the modes in which men have been led, or are now being led, to define not only the ways, and varieties of ways, in which each imponderable acts, but also to estimate by those measurements to which men appear in material things, the amount or value (if the word be preferred) of that work in material things done by these imponderable elemental powers. To do this involves references, perhaps, in a few words, to conclusions at which a life of self-devotion to one cause may have arrived, that life, too, being aided by the very highest of cultivated mental intelligence and the capability of employing such powers of scientific research, the very alphabet of which is beyond the attainment of the majority of men.

Whilst thus frankly, and at the outset, admitting how high a class of mind is required for these original investigations, it must not be overlooked that the principles which have governed the researches of these men, and the conclusions at which they have arrived, may be appreciated by many minds.

When the late Mr. Faraday was discoursing "On the

* The Cantor Lectures, delivered before the Society of Arts.

Conservation of Force," he made a statement in relation to an observing and a mathematical mind which will have more weight by your generalisation of his words than by my dilution of them. Hence this quotation:—

"It may be supposed that one who has little or no mathematical knowledge should hardly assume a right to judge of the generality and force of a principle such as that which forms the subject of these remarks. My apology is this:—I do not perceive that a mathematical mind, simply as such, has any advantage over an equally acute mind not mathematical in perceiving the nature and power of a natural principle of action. It cannot of itself introduce the knowledge of any new principle. Dealing with any and every amount of static electricity, the mathematical mind can, and has, balanced and adjusted them with wonderful advantage, and has foretold results which the experimentalist can do no more than verify. But it could not discover dynamic electricity, nor electro-magnetism, nor magneto-electricity, or even suggest them; though, when once discovered by the experimentalist, it can take them up with extreme facility. So, in respect to the force of gravitation, it has calculated the results of the power in such a wonderful manner as to trace the known planets through their courses of perturbations, and, in so doing, has discovered a planet before unknown. There may be results of the gravitating force of other kinds than attraction inversely, as the square of the distance of which it knows nothing can discover nothing, and can neither assert nor deny their possibility or occurrence."*

Influenced by such views as these, it seemed that no disrespect to the highest intellect could accrue from an attempt to make clear, even to the lowest, a few of the fundamental principles from which important truths have been evolved. It must be borne in mind that to illustrate the modes by which these energies have been measured and utilised, and not to make any attempt at measuring them, is the leading principle which, thus early enunciated, may prevent misconceptions of the title.

The very words, "Energies of the Imponderables," are, to some minds, terms and not realities—symbols, like political watch-words, serving only to classify their professors—things for *savans* to discourse upon—provinces in that intellectual dreamland in which natural science is supposed to dwell. To the majority of men, to those who toil for their daily bread, and, with all their toiling, find but scant supply, the monastery of science, in which her monks live apart from the world and all its vulgar cares, seems a paradise in which is no unrest. Such is only one of many thousand delusions. Within the thinly-peopled world of those who investigate the laws of Nature, there are all the pleasures and pains which meet the labourer with his spade, the mechanic with his tools, the merchant in his office, or the statesman in his cabinet. It is because students and investigators of Nature's laws live much alone—because they cultivate a species of clanship—because there is amongst them a kind of Hindoo caste—that they are seldom in contact and companionship with the toilers in material things. This is much to be regretted. Although both parties are losers, yet the toilers in material things are by far the greatest losers.

Such men as these are the true pioneers of the human race, and that army is ill-directed which allows the work of preparation done by its pioneers to be so far in advance that the mountains they had levelled were again piled up, the rivers they had dried were again flowing, and the thorns once cleared from the desolate prairies were again rendering the ground unfertile. The men of science are they who give the sap of vitality to the tree of commerce. Society plucks the fruit, and seldom waters the plant. Such has been, and such still is, the case with investigators of natural science, if the men amongst whom they live take the fruit and care neither for the gardeners nor the garden.

Look at the world—the beautiful glass in some of our

stained windows is a lost art. Look at the temples in India, illustrations of which the photographs so truthfully reproduced in this room a few weeks since. Civilised Europe and self-satisfied England cannot, either by their St. Peter's at Rome or those recent productions which we are bound to recognise as the highest attainment of national architecture,—the Albert Hall and adjacent memorial,—approach even at a distance. These temples of a religious profession, with which we are not even acquainted, and of which no records remain, abound in an architecture with which neither in its conception nor in its detail have we ought to compare. And of the materials the men of that age used, we may say the stone is stone still; the sharpness of the carvings is sharpness still.

Is all our dolomite a bastard dolomite? Why are we in England obliged to seek for Italians to form our moulds—to pour in the clay, and to sculpture the marble? Why do we go to Germany for our draughtsmen, our science, and our music, and to France for our adornments and our designs?

One illustration of the neglect of obviously social gain from want of scientific attention cannot, in this room, be out of place.

The Society of Arts was founded in 1753, and when the scientifically practical and theoretical minds of Count Rumford and others considered on what basis and why the "Royal Institution of Great Britain" should be founded, they expressed the objects of thus founding a Society which should supplement the work of the Society of Arts in the following title-page to the charter of 1800:—

ROYAL INSTITUTION
OF
GREAT BRITAIN,
For Diffusing the Knowledge and Facilitating the General
Introduction of
USEFUL MECHANICAL INVENTIONS & IMPROVEMENTS,
And for Teaching by
COURSES OF PHILOSOPHICAL LECTURES AND EXPERIMENTS
THE
APPLICATION OF SCIENCE
TO THE
COMMON PURPOSES OF LIFE.

In reference to the necessity for so supplementing the work done here by our predecessors, in order to "advance the applications of science to the common purposes of life," the then managers state that "the giving of premiums to inventors was done by a most respectable society (the Society of Arts), but to diffuse knowledge needed another incorporation."

Whilst admitting how nobly the Royal Institution has done good work, and how generations yet unborn will look back with reverential gratitude to the boons which those who have laboured within its walls have conferred upon men, it is curious to mark how the views of its founders, and the one great purpose of its formation in 1800, are being realised by the Society of Arts in 1873.

In 1800 the managers of the Royal Institution, as their first act, constituted fourteen committees, for the following purposes;—

1. To investigate the various processes used in making bread, with a view to their improvement.
2. To investigate means for producing cheap and nutritious soups for feeding the poor.
3. Improvement of cottages and cottage fire-places.
4. Improvements in the construction of stoves for warming dwelling-houses.
5. Improvements in kitchen fireplaces and kitchen utensils of private families.
6. Improvements of the most useful articles of household furniture.
7. To ascertain, by experiment, the effects of various processes of cookery upon the food of cattle.
8. Improvement of kitchen fireplaces and kitchen utensils used on shipboard.
9. Improvement of lime-kilns.
10. Ascertaining the effects of mixing clay, &c., with coal-dust and cinders, in forming fire-balls and combustible cakes.

* *Proc. Roy. Inst.*, Feb. 27, 1857, p. 364.

11. Improving the composition of mortar and cements.
12. To ascertain the best method of building cottages and farm-houses with earth rammed together.
13. A committee of mechanics for the improvement of useful machines of all descriptions.
14. A committee for improving the various processes necessary in producing iron from its ores, and in working and refining of iron and steel.

Thus did one noble foster-child of this Society prescribe its own duty, and, child-like, neglect that particular duty; and now that the child has attained the age of threescore years and ten, the nursing mother, by gold medals and money rewards, steps forward to complete the work begun by her foster-child,* and further, by these annual Cantor Lectures, she now does that which—not being done in 1800—led to the formation of the "Royal Institution of Great Britain."

This comes of the people of a country allowing the science of a country to dwell alone. All advances are first suggested by men who observe and think; they are extended by men who reason and test; they are utilised by men who act.

The pioneers of an army are not the fighting men; sailors navigate the ship; marines do the warfare.

The men who investigate the laws which govern the energies of the imponderables are not the men to utilise and apply them. The practical knowledge,—the stimulus of interest,—the capital of the manufacturer, are wanting to the philosopher; while the manufacturer on his part is equally in want of the general information and accurate reasoning of the man of science. When the commercial element enters, and another object of regard is set up for worship, the man of science cannot serve two masters; he cannot serve science and mammon. The more earnestly and heartily he serves the former, the less he bows to the latter. The service of natural science has within itself far more ennobling mental rewards than mammon can confer.

Longfellow, in his letter to Agassiz, on his fiftieth birthday (28th May, 1857), after alluding to the sacrifice he made of his country and his home, for the cause of natural history, well expresses what he feels who, single-minded, teaches men to read what is still unread in the manuscripts of God. Agassiz is described as—

"He who wandered away and away,
With Nature, the dear old nurse,
Who sang to him night and day
The rhymes of the universe."

And then comes a reward more welcome than money or honours—

"For whenever the way seems long,
Or his heart begins to fail,
Nature sings a more wonderful song,
Or tells a more marvellous tale."

This course of Cantor Lectures, in relation to the energies of the imponderables, is to be an attempt to occupy the border-land between pure scientific research and the ministration to social needs; to tread, in fact, upon neutral ground, to launch our boat upon the Rubicon

* A sum of £500 having been placed at the disposal of the Council of the Society of Arts, through Sir William Bodkin, by a gentleman who does not wish his name to appear, for promoting, by means of prizes or otherwise, economy in the use of coal for domestic purposes, the Council have decided to offer the following prizes:—(1). For a new and improved system of grate suitable to existing chimneys as generally constructed, which shall, with the least amount of coal, answer best for warming and ventilating a room.—The Society's Gold Medal and Fifty Pounds. (2). For a new and improved system of grate, suitable to existing chimneys as generally constructed, which shall, with the least amount of coal, best answer for cooking food, combined with warming and ventilating the room.—The Society's Gold Medal and Fifty Pounds. (3). For the best new and improved system of apparatus which shall, by means of gas, most efficiently and economically warm and ventilate a room.—The Society's Gold Medal and Fifty Pounds. (4). For the best new and improved system of apparatus which shall, by means of gas, be best adapted for cooking, combined with warming and ventilating the room.—The Society's Gold Medal and Fifty Pounds. (5). For any new and improved system or arrangements, not included in the foregoing, which shall efficiently and economically meet domestic requirements.—The Society's Gold Medal and Fifty Pounds.

which divides the provinces of science from those of commerce. It does not aspire to any claim on the nests of science; they who build them are welcome to the imagined and worthless immortality of a name. It does not propound to commerce new modes of amassing wealth. They may keep their wealth who can. But it does seek to bring before those whose daily bread and daily luxuries are derived from science, illustrations of some of the truths on which their daily labour rests. It will try to do this in plain and simple form, divested of those higher studies through which these truths have been in some measure attained, and in a thousand ways extended.

That the work is one worthy of all human intelligence may be inferred from the official document given by the authorities of that incorporation of men who are the real rulers of the earth, properly so called. Statesmen and politicians may influence the minds and bodies of men, but engineers influence all material things.

The Institution of Civil Engineers, established in 1818, long before passenger railways, telegraphs, &c., &c., were known, and now numbering among its members men in all parts of the globe, clearly and aptly defined the objects of their incorporation in words well fitted to the purposes of our present consideration. They then (in 1818) defined the object of their association to be "The acquisition of that species of knowledge which constitutes the profession of a civil engineer, whereby the great sources of power in nature—i. e., the energies of the imponderables—are converted, adapted, and applied for the use and convenience of man."

It may be said, and with some show of reason, when the comprehensive title of these lectures is considered, a little well or completely done is better than much ill or very partially done. As a principle in education this is a truism which the Committee of Council on Education and our various School Boards would do well to adopt and illustrate; but these Cantor Lectures are not to be scholastic lessons; they may teach, but the primary object of them is rather to be suggestive of thought—to give the minds of hearers and readers food for reflection, material for development, to arouse inquiry, to provoke investigation; to leave, in fact, an unsatisfied impression that there is more than the lecturer has expressed—and there is much for hearers and readers to consider. If thus they only lay in the foundations of knowledge, and in rough and sketchy outline show the superstructure, they will have done good service—they will have stimulated research, and so led to the acquisition of knowledge and a habit of mind more valuable far than any which can be given from this platform to you who sit at ease on those cushioned seats, willing to rest for a while under the delusive spell that the Society of Arts has thus found a right royal road (and perhaps a pleasant one) to learning. Such an unsatisfied feeling in relation to the energies named, and the measurement and utilisation of them, it is the object of this course to endeavour to create. If this result be attained, then in those future years, when by individual labour present difficulties are overcome, and light shines where thick darkness now over-spreads, there will be cause for thanks, where, perhaps, when these lectures end, an unsatisfied longing may alone be found.

(To be continued.)

CORRESPONDENCE.

ACETAMIDE AND ETHYLATE OF SODIUM.

To the Editor of the Chemical News.

SIR,—My letter, which does not seem to please Mr. Hartley, has caused him to rectify an error into which he is reported to have fallen.

According to the report in the CHEMICAL NEWS, Mr. Hartley said that ammonia is given by the action of

acetamide on ethylate and methylate of sodium. Dr. Armstrong, too, is reported to have obtained ammonia in the same manner. The truth appears to be, however, that acetamide yields no ammonia by action on ethylate and methylate of sodium; but that soda acetamide and caustic soda yield ammonia, and caustic soda always accompanies ethylate of sodium, unless very special precautions be taken to ensure its absence.

Whether Mr. Hartley and Dr. Armstrong said what they are reported to have said, is a question between them and the reporter. My object in writing my letter was to rectify an error, and I believe that I have attained it.—I am, &c.,

J. ALFRED WANKLYN.

London, June 30, 1873.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Under this heading will be found an encyclopaedic list of chemical papers published abroad during the past week, with abstracts of all susceptible of advantageous abridgment. The two half-yearly volumes of the CHEMICAL NEWS, with their copious indices, will, therefore, be equivalent to an English edition of the "Jahresberichte."

NOTE. All degrees of temperature are Centigrade, unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances de l'Académie des Sciences, June 9, 1873.

Presence of Avic Acid in a Sample of Guano, and Remarks on the Estimation of the Commercial Value of Manures in Accordance with their Elementary Composition.—E. Chevreul.—In May, 1866, the author discovered in the suint of sheep a substance to which he gave the name of elic acid. It is perfectly liquid below 16°, and becomes somewhat viscous at 15° to 14°. In 1869 he extracted from this elic acid another substance which he named avic acid, because it had a "smell of birds." In 1871 he accidentally recognised the same acid in the feathers of an albatross. He now maintains that he has discovered the same principle in guano. This leads him to urge the importance of immediate or proximate organic analysis as applied to manures in contradistinction to mere ultimate or elementary analysis. The most important study for the progress of agriculture is the determination of the immediate principles of soils and manures, and that of their organoleptic properties. As regards manures, the great point is the study of their immediate principles viewed in relation to the immediate principles of the chief arable soils. The author has shown how soils of different natures act differently with regard to the oily principle which is one of the ingredients of colza oil-cake. The neglect of the proximate analysis of manures explains why avic acid has not been recognised in guano. In analysing some new samples of that manure from Peru he found avic acid, along with carbonate of ammonia in the first, nearly colourless, washings with water. Its odour is not distinctly perceptible until the carbonate of ammonia has been completely evaporated. Guano, he finds, can be entirely freed from carbonate of ammonia by a temperature of 90°.

Researches on New Derivatives of Propyl.—A. Cahours.—He prepares glucinium propyl by acting upon mercury propyl with the finely-divided metal at the temperature of 130° to 135° in a sealed tube. It is a colourless liquid, boiling at 244° to 246°, and giving off dense fumes without becoming ignited. If cooled to -17° it takes the appearance of a fatty oil. Water decomposes it with violence, producing a copious evolution of gas, and an abundant deposit of hydrated glucina. By a similar process he has prepared glucinium-ethyl; which boils between

185° and 188°, and gives off inflammable vapours. Water decomposes it in the same manner as glucinium-propyl. It is also attacked by absolute alcohol, the sides of the tube becoming covered with a transparent crystalline substance. By acting with chloride of silicon upon anhydrous propylic ether the author has obtained compounds analogous to Ebelmen's orthosilicic ether, and to the silicic, mono-, di-, and trichlorhydrines of Friedel and Crafts. The bodies thus obtained are silico-propionic ether, and silico-propionic-, mono-, and dichlorhydrines. Boropropylic ether was obtained by passing very slowly a current of perfectly pure chloride of boron into anhydrous propylic alcohol maintained at a temperature bordering upon zero. The compound in question is represented by the formula $\text{Bo}(\text{C}_6\text{H}_7\text{O}_2)_3$. Liebig and Wöehler obtained a crystalline product, known as allophanic ether, by causing the vapour of cyanic acid to act upon absolute alcohol. Hofmann obtained the same compound by allowing alcohol to act upon urea in a cohobator. In this case the formation of allophanic ether is constantly accompanied by that of urethane or carbamic ether. The author, by replacing ethylic alcohol with propylic alcohol prepared propylic allophanate in nacaceous laminæ, sparingly soluble in cold water, but readily soluble in boiling water and alcohol, and fusible between 150° and 160°. Its composition is $\text{C}_{10}\text{H}_{10}\text{N}_2\text{O}_6$. Propyl-urethane, $\text{C}_8\text{H}_9\text{NO}_4$, is obtained in the form of long, colourless, brilliant crystals, easily soluble in water, alcohol, and ether. It fuses between 51° and 53°, and boils at 194° to 196°. If moist it is decomposed by heat, and yields large quantities of ammonia.

Part Played by Atmospheric Nitrogen in Vegetation.—P. P. Dehérain.—The author has previously announced that he had succeeded in fixing atmospheric nitrogen upon the black matters formed during the decomposition of the hydrates of carbon. In more recent experiments he has shown that this fixation takes place at common temperatures, and that it is due to the formation of ammonia. Thus, in one of his experiments the absorbent matter was glucose and ammonia; amount of free nitrogen at the beginning of the experiment, 38 c.c.; ditto, at the conclusion, 21 c.c.; nitrogen taken up, 17 c.c., or 44.7 per cent of the original amount. The presence of cyanides could not be recognised in any of these experiments. It is established that the fixation of nitrogen by carbonaceous matter which takes place at 100° ensues also in the cold, though with less energy. An atmosphere poor in oxygen favours the fixation.

Boiling-Points and the Molecular Volumes of the Chlorated Isomers of the Ethylic Series.—G. Hinrichs.—A physico-mathematical paper.

Ethylacetylen formed Synthetically, and on its Identity with Crotonylen.—L. Pruner.—Ethylacetylen has been formed synthetically by Berthelot, who caused acetylen to act directly upon ethylen at a dull red heat. Crotonylen was discovered by Caventon, who removed 2 equivalents of hydrobromic acid from the bromide of butylen. The mixture of ethylene and acetylene was passed into bottles containing bromine. The bromised liquids, being left for two days in contact with a slight excess of bromide, are passed into tetrabromide, $\text{C}_8\text{H}_6\text{Br}_4$. On expelling the alcohol and crystallising, the compound thus obtained was found to agree in appearance, in properties, and especially in point of fusion with, the tetrabromide of crotonylen described by Caventon.

Synthesis of Phenylallyl.—C. Chojnacki.—The author obtained phenylallyl by heating to 100° under pressure a mixture of equal parts of benzin, and of iodide or bromide of allyl with one-fifth of zinc-powder.

Combinations of Chloride of Titanium with the Ethers.—E. Demarcay.—The author has formed and examined a number of these compounds, which he considers as chlorhydrines analogous to the silicic chlorhydrines of Friedel united to chlorides of the acid radicals. The sulphides and sulphydrates of the alcohol radicals

behave with chloride of titanium in the same manner as normal ether.

On Phenocyanine.—T. L. Phipson.—(see xxvii., p. 299.)

Remarks on Mène's Observations on the Manufacture of Sulphate of Ammonia from Nitrogenous Refuse.—L. L'Hôte.—The process for manufacturing ammoniacal salts patented by Martin, and which Mène pronounces impracticable, consists essentially in the substitution of lime, baryta, &c. for soda-lime. In some cases caustic soda alone is required. The azotised matter is first attacked with caustic soda-lye at 10 per cent, and the mass is afterwards made into a paste with slaked lime. On distillation the combustion of the organic matter is as complete as in the determination of nitrogen by the soda-lime process, and the residue contains neither nitrogenous charcoal nor cyanides.

Determination of Phosphoric Acid in Manures, Coprolites, Phosphatic Minerals, &c.—Ch. Mène.—A critique on the process of Joulie (CHEMICAL NEWS, xxvii. 228, 309, 314). The citrate of ammonia process consists in treating the manure with dilute nitric or hydrochloric acid, and filtering off the insoluble matter. To the clear filtrate is added ammonia, which generally forms an abundant white precipitate. Citric acid is then added till the precipitate re-dissolves, and any insoluble particles are removed by filtration. To the filtrate is added sulphate of magnesia, and then more ammonia. The resulting precipitate is regarded as ammonia, magnesian phosphate, &c., is filtered, washed, and calcined. Without wishing to show how this analysis is faulty, the author insists, on the one hand, on the solubility of ammonia magnesian phosphate in ammoniacal salts, and, on the other, on the precipitation of all the gelatinous silica, which is then estimated as ammonia magnesian phosphate. To be convinced of this it suffices to take a few drops of silicate of soda diluted with water, to add ammonia which gives a precipitate soluble in citric acid, but capable of being precipitated afresh by ammonia. Alumina under the same conditions is not re-precipitated. To give an idea of the error which may be committed Mène quotes the results of an experiment when a fossil phosphate, by the citrate of ammonia process, gave 70 per cent tribasic phosphate of lime, but by Chancel's method—the bismuth process—it yielded only 1·5 per cent. The author agrees with Joulie in his condemnation of the ammonia process (Bobbier's) but recommends in its stead that of Chancel, which he himself has used for ten years, and which is exempt from all errors in excess. (We think it deplorable if any analytical chemist is ignorant of the means for rendering gelatinous silica insoluble in dilute acids, thus avoiding the error in excess pointed out by M. Mène).

Bibasic Sulphate of Lead from Ariège.—Ed. Jannettaz.—The author finds this mineral identical with the bibasic sulphate of Leadhills. He remarks as a strange circumstance that the specimens of Lanarkite examined by Thomson and Brooke should, according to both these authorities, contain a half equivalent of carbonic acid, and should yet agree in their characters with the crystals from Ariège and Leadhills, which contain none.

Extract from Memoir on the Various Causes which Produce Strokes of Lightning.—M. de Fonvielle.

—The author seeks to show that two neighbouring conducting objects react powerfully on each other under the influence of a thunder-cloud, and that this reciprocal influence varies according as they are insulated or connected one or other, or both, with the common reservoir; also that a thunder-cloud produces, by the fact of its movement, special reactions—like the plate of a Holtz machine. The induction on the earth's surface he points out must often be strong enough to affect the passage of clouds, giving them a greater velocity before they reach the zenith of the object electrified, or retarding them after they have passed the zenith; and this fact he compares with certain attractions and repulsions between stars, observed by

Hansteen and others, and doubtless due to magnetic force; which force appears to have been neglected as being in juxtaposition with that of gravitation: just as the displacement of clouds above referred to is combined with that produced by the wind. The changes in terrestrial magnetism in consequence of star motions are analogous to those which clouds produce in the electrification of the terrestrial surface.

Theory of Sun-Spots, and the Dark Nucleus of the Sun.—M. Vicaire.—This note refers chiefly to M. Respighi's observation of a sinking of the chromosphere at the spots. For this to yield valid support to the cyclonic theory, it must be shown (the author holds) that, supposing the depression certain, (and it has been contested by P. Secchi), it is really due to an engulfing of the chromosphere, and that a turning movement may be there observed; such movement being quite an exceptional phenomenon. Further, according to M. Faye's own calculations, the centrifugal acceleration in the solar cyclone would be only $\frac{1}{11}$ of what produces the terrestrial cyclone. Now the depression of the photosphere at the spots, and also, according to M. Respighi, that of the chromosphere, is equal to several thousands times that produced by terrestrial cyclones. Indeed, a fall of 4 c.c. in the barometric column corresponds at the sea-level to a displacement in altitude of 430 metres or $\frac{1}{13000}$ of the earth's radius, and it is known that there are solar spots the depth of which exceeds this radius. Hence the cause assigned for the spots by M. Faye would be only $\frac{1}{15000 + 181}$ or nearly $\frac{1}{2500000}$ of the intensity required by the phenomenon. M. Vicaire adheres to Wilson's theory of the sun's composition.

Researches of Spectral Analysis on the Subject of the Solar Spectrum.—Mr. J. N. Lockyer.—A recent communication to the Royal Society.

Reply to Preceding Note of M. Raynaud on the Maximum Resistances of Magnetic Coils.—M. du Moncel.

Relation between Electrical and Capillary Phenomena.—M. Lippmann.—When a drop of mercury in a glass vessel and, covered with sulphuric acid, is put in communication with a point of copper or iron passing through the acid, it suddenly becomes more convex, and an electric current is produced which polarises the surface. The surface contraction is due to a change of capillary constant; this and the electromotive force of polarisation are continual functions of each other. Reciprocally, an extension of surface produced mechanically polarises it as an electric current would. M. Lippmann varies the capillary constant of a surface of mercury in a glass tube, by polarising it with a current from a Daniell element, causing a deformation of the meniscus. He constructs a very sensitive capillary electrometer (for measuring electromotive forces), consisting of a thin glass tube of mercury, which he puts under the object-glass of a microscope for observation of the meniscus as affected by the current. Replacing the pile in the above case by an electrometer or galvanometer, and displacing the mercury mechanically, it can be shown that the electromotive force is varied, the quantity of electricity being independent of the form of the surface, and simply proportional to the area. He also constructs an electro-capillary motor. Two masses of mercury in acidulated water serve alternately as negative electrodes to the current of a Daniell element. In each mass are partially immersed a set of glass tubes open at both ends. At each inversion of the current one set rises, the other descends, and this alternate movement is transformed, by levers, &c., into one of rotation.

Magnetic Observations.—M. Diamilla Müller.—The author has established a temporary magnetic observatory on a hill near Florence, and shortly before the recent eclipse he noticed a stoppage for three quarters of an hour, of the oscillations in his magnetometer (which took on an average twenty seconds), and when they resumed they were much smaller and slower. He thinks this may be due to the special position of sun, moon, and earth, and

not to the eclipse; but invites observation of the oscillations of the needle at the approach of each new moon. He also gives results of the second series of simultaneous magnetic observations made in various parts of the globe on October 15 last. It appears—(1) That the secular variation of the declination is inversely proportional to the distance of the place of observation from the magnetic equator; (2) that the secular variation of the inclination is proportional to the extent of their magnetic parallels; (3) that the secular variation of the intensity (total force) is proportional to the secular variation of the inclination.

Spectroscopic Researches on the Fumeroles of the Eruption of Vesuvius in April, 1872, and Actual State of the Volcanos.—Extract from letter of M. Palmieri's to M. Sainte-Claire Deville.—The writer states that Vesuvius has become very quiet; and that he has found thallium in most of the fumerole sublimations (by spectral analysis) and, in some cases, a product rare in Vesuvius, viz., boric acid.

Reimann's Färber Zeitung, No. 21, 1873.

On Petroleum Benzin.—The author describes the petroleum benzin now coming into use as a substitute for benzol. The new fluid is equally useful for dissolving out fatty and resinous matters, but cannot be used in the manufacture of aniline.

Dyes for Wool.—Receipts are given for a sulphur fast puce, a fast drab, sad green with vat-blue bottom, fast violet with vat-blue and grain, madder drab, dark green, madder ponceau topped with grain.

Alpaca.—Silver grey and brown.

Dyes for Cotton.—The editor gives formulæ for a dull yellowish green, a cinnamon-brown, and a light brown.

Straw Hats with Aniline Colours.—The editor directs that if an aniline colour does not take on from a lukewarm solution, the straw-ware should be steeped in a hot solution of glue, then wiped with a cloth, and placed in the colour-bath.

Manufacture of Magenta without Arsenic.—Meister Lucius, and Co., of Höchst-on-the-Main, are manufacturing magenta by the action of nitro-benzol upon aniline or toluidine. Couper maintains that he patented as early as 1866 a process essentially the same.

Oil Colours for Printing.—The following mixture has been recently patented:—13 parts of varnish (what kind?), 5 of oil of turpentine, 1 of white wax, 1 of rosin or, instead, boiled linseed oil, 1 of half-boiled linseed oil, 0.20 of wax (?), 1.98 crude turpentine. Silk, woollen, and cotton tissues can be printed with this composition, and the colours do not wash off.

Annalen der Chemie und Pharmacie, band clxvii., hefts 2 and 3. (Neue Reihe, band xci., 2 and 3.)

On Phenanthren.—M. Hayduck.—Phenanthren crystallises in colourless, shining, occasionally rather large, crystalline scales; melts at 96°; begins to sublime at 100°; and passes over unchanged at higher temperatures. It is readily soluble in hot, and moderately in cold alcohol; and dissolves easily in ether, benzol, bisulphide of carbon, and glacial acetic acid. The solutions display a fine blue fluorescence. It dissolves with a green colour in concentrated sulphuric, and also in nitric acid. Ostermeyer and Graetle have observed that a sulphacid and a nitro compound are formed under these circumstances. A hydride of phenanthren is not formed even on the prolonged action of sodium amalgam upon the alcoholic solution. Its formula is $C_{14}H_{10}$, and its composition is as follows:—Carbon, 94.4; hydrogen, 5.6; total, 100.0. The author has examined the picrate—phenanthren dibromide, $C_{14}H_{10}Br_2$; bromphenanthren, $C_{14}H_9Br$; dibromphenanthren, $C_{14}H_8Br_2$; tribromphenanthren, $C_{14}H_7Br_3$; the chinon, $C_{14}H_8O_2$; and the dibromchinon, $C_{14}H_6Br_2O_2$. From this compound the author attempted, though unsuccessfully, to obtain an isomer of alizarin.

On the Compound $C_{14}H_8S_2$.—C. Paulz.—An account of the preparation, properties, and combinations of this as yet unnamed substance.

On Chlorosulphides of Carbon.—B. Rathke.—A lengthy paper, which does not readily admit of abstraction.

Action of Amides upon $CSCl_4$ and $CSCl_2$.—B. Rathke.—Also unsuitable for abstraction.

Transformation of Nitric Compounds into Sulphon Acids.—B. Rathke.—On the prolonged digestion of nitroformendisulphon potassium, $CH(NO_2)(SO_3K)_2$, in the water-bath the quantity of the salt decreases, and a salt is obtained which does not contain the nitro group. This new salt has the composition of formentrisulphon potassium, $CH(SO_3K)_2 + H_2O$.

Researches on the Allyl Group; on β -Bibromopropionic Acid.—G. Münder and B. Tollens.—A long and exhaustive paper not adapted for abstraction.

Transformation of β -Bibromopropionic Acid into Acrylic Acid.—W. Caspary and B. Tollens.—The authors have prepared and examined the acrylates of silver, lime, strontia, and acrylic methyl-, ethyl-, and allyl-ethers.

Constitution of the Allyl- and Acryl-Derivatives.—B. Tollens.—A lengthy theoretical paper.

On Articles of Diet in General, and on the Value of Liebig's Extract of Meat as a Constituent of Human Food.—Max von Pettenkofer.—An important communication, to which we shall return on a future occasion.

Dry Distillation of Formiate of Lime.—A. Lieben and E. Paterno.—The principal product obtained is methylic alcohol.

On Paralactic Acid, the Optically-Active Lactic Acid of Flesh.—J. Wislicenus.—A valuable and exhaustive paper.

Supplement to Researches on Certain New Derivatives of Sulpho-Carbaminic Acid.—MM. Hlasiwetz and Kachler.—The authors find that their results had been anticipated by Zeise as far back as 1842.

Spontaneous Combustion of Hay.—H. Ranke.—The author finds that, in consequence of prolonged fermentation, hay can become transformed into a true coal, which, when exposed to the air at somewhat elevated temperatures, acts as a pyrophorus.

Bulletin de la Societe d'Encouragement pour l'Industrie Nationale, No. 247, July, 1873.

Note on Rich and Pure Ores of Iron found in France.—M. Gruner.—The author points out various localities in France where brown hæmatite, mangiferous spathic iron, oligistic iron ore, and pure magnetic oxide are found in quantity.

Graniér's Apparatus for Testing the Inflammability of Petroleum Oils destined for Lighting Purposes.—Report by V. de Luynes.—A small cylindrical receiver, of metal, is closed by a movable lid, provided with a circular aperture in its centre. This receiver is filled to two-thirds its volume of the oil to be tested, so that there remains between the lid and the surface of the oil a space full of air, with which the inflammable vapours furnished by the oil may mingle. A tube, soldered to the bottom of the receiver, holds a wick, whose upper extremity is in the middle of the aperture in the lid, whilst a thermometer plunged in the oil gives its temperature. To make a test, the oil is poured into the receiver to the height required; the wick is saturated with it, and lighted. The oil of the wick, burning, heats the oil till the temperature is reached, when inflammable vapours are given off. A slight explosion then ensues; the wick is extinguished, and the degree on the thermometer is read off. Petroleum-oils sold for lighting purposes in France are required to be colourless, to weigh 800 grms. per litre, and not to inflame at temperatures below 35°.

PATENTS.

ABRIDGMENTS OF PROVISIONAL AND COMPLETE SPECIFICATIONS.

An improved clinical thermometer. Henry Joseph François Hubert Foveaux, surgical instrument maker, 62, Strand, Middlesex. November 29, 1872.—No. 3591. This invention consists in making clinical thermometers with one or more flat sides, or placing projections thereon, to keep them from rolling upon any smooth or inclined surface upon which they may be placed, and thereby being broken. The construction preferred is a single flat surface to form the back, the front being semicircular or of any curve, this make combining with the security from rolling, due to the flat surface, the advantage of making the index appear more prominent.

Improvements in magnetic therapeutic plasters. Philip William Seymour, Surrey Lane, Battersea, Surrey. November 29, 1872.—No. 3600. The invention consists in forming a therapeutic plaster of a composition of iron-filings and any suitable adhesive matter spread upon a woven fabric, said iron-filings being afterwards magnetised.

A new and improved method of and apparatus for staining or dyeing velvets and all other woven fabrics, and for producing designs and figures thereon. John Carter Ramsden, manufacturer, Smith House, Lightcliffe, Halifax, and James Marsland Tankard, worsted-spinner, Bowling Hall, Bradford. November 30, 1872.—No. 3616. We utilise and apply, for the purpose of staining or dyeing pile fabrics or other similar goods, the different gases and vapours which arise from the slow combustion, decomposition, or distillation of the organic products of ligneous origin, or any other combustible from which the different hydrocarbon gases and volatile productions can be evolved. The gases and vapours are caused to pass into a receiver, within which condensation takes place, and a coloured deposit will be found upon the fabric placed therein. For producing patterns stencil plates or some similarly contrived patterns are laid upon the fabric, in which case the whole of the fabric will be coloured except where the patterns are. This method is applicable to other than pile fabrics.

New and improved methods or processes of and apparatus for staining or dyeing fibrous filaments when in the raw or when in a partly prepared state. John Carter Ramsden, manufacturer, Smith House, Lightcliffe, Halifax, and James Marsland Tankard, worsted-spinner, Bowling Hall, Bradford. December 2, 1872.—No. 3620. The said fibrous filaments are first saturated either wholly or in part by some chemical solution, say of acetate of lead, dissolved in water, and are then placed in an air-tight chamber, and are acted upon by the gases and vapours arising from the slow combustion, decomposition, or distillation of the organic products of ligneous origin, or any other combustible from which the different hydrocarbon gases can be evolved after the manner described by us in a provisional specification filed in the Great Seal Patent Office on the 30th day of November, 1872. In some cases it will be found advisable to dispense altogether with the use of the said gases and vapours and the same receivers, and use as an equivalent bisulphide of carbon.

The preparation of an extract from the berries of the mountain ash (pyrus) (German, Eberesche). Christian von Hennings, Hamburg. December 2, 1872.—No. 3628. The object of this invention is to prepare an extract from the berries of the mountain ash, suitable more especially for being used in cases of colds and influenzas.

Improvements in the mode of and apparatus for preparing lime for the treatment of sewage. Major-General Henry Young Darracott Scott, C.B., and Thomas Walker Scott, Ealing, Middlesex. December 4, 1872.—No. 3670. The main object of our invention is to economise labour when treating sewage with lime for the purpose of defecation and utilisation. Tanks or vessels are used with stirring apparatus with horizontal or inclined arms, from which are suspended metal baskets or perforated boxes containing the lump lime.

A new apparatus for distilling, concentrating, and evaporating. Farnham Maxwell Lyte, chemist, of the firm of Storck and Co., Asnières, France. (A communication from Henri Storck, Edouard Hentsch, Auguste Hentsch, André Lutscher, and Frédéric Grininger, constituting the firm of Storck and Co., and Armand Decottegnie, manufacturer, Asnières, France). December 5, 1872.—No. 3685. The features of novelty of this invention consist essentially in distilling, evaporating, and concentrating liquids in improved apparatus, the principle of which consists in a mode of heating (under increased or diminished pressure, or in *vacuo*) certain cylindrical, conical, or rounded surfaces, and bringing the liquid to be treated into contact with those surfaces in thin streams or films, so that the liquids in passing over a large extent of heating surface may be rapidly distilled, evaporated, or concentrated. The heating surface is divided exteriorly into compartments, which retain the liquid in contact therewith until evaporation is completed.

BERNERS COLLEGE of CHEMISTRY.— EXPERIMENTAL MILITARY and NAVAL SCIENCES, under the direction of Professor E. V. GARDNER, F.R.S., &c., of the late Royal Polytechnic Institution and the Royal Naval College. The Laboratory and Class Rooms are open from 11 to 5 a.m., and from 7 to 10 p.m. daily.

Special facilities for persons preparing for Government and other examinations.

Private Pupils will find every convenience. Analyses, Assays, and Practical Investigations connected with Patents, &c., conducted.

For prospectus, &c., apply to Prof. E. V. G., 44, Berners-street, W.

Analysis of Food, Water, and Air.—Mr. WANKLYN has opened a Laboratory at 117, Charlotte Street, Fitzroy Square, and is prepared to give Practical Instruction in Chemical Analysis to Medical Officers of Health, and to persons proposing to undertake the duties of Public Analysts under the new Act.

North London School of Chemistry, Pharmacy, &c.—Conducted by Mr. J. C. BRAITHWAITE, for thirteen years Principal Instructor in the Laboratories of the Pharmaceutical Society of Great Britain, and Demonstrator of Practical Pharmacy, Pharmaceutical Latin, &c.

The Session 1872-1873 will commence on the 1st of October when—

The LABORATORY will be open at 10 a.m. for Instruction in Practical Chemistry as applied to Pharmacy, Medicine, Analysis, &c. Terms moderate.

The CLASSES will meet as usual.

The CHEMICAL and TOXICOLOGICAL CLASS on Monday and Thursday evenings at 8 p.m., commencing October 1st.

The LATIN CLASS on Tuesdays and Fridays at 8 p.m., commencing October 2nd.

The MATERIA MEDICA and BOTANICAL CLASS, every Wednesday and Saturday at 8 p.m., commencing October 3rd.

The BOTANICAL GARDEN affords to Students desirous of acquiring a Practical Knowledge of Botany every facility for doing so. During the Season BOTANICAL EXCURSIONS are made every Saturday at 10 a.m.

Fee to either of the above Classes Half-a-Guinea per Month. Pupils can enter at any period to either Classes or Laboratory.

All Fees must be paid in advance.

PRIVATE TUITION for the usual Examinations of the Society, the Modified Examination, &c.

Letters of inquiry should be accompanied with a stamped envelope.

Address—54, KENTISH TOWN ROAD, N.W.

Royal Polytechnic Institution, 309, Regent Street.—Laboratory (entirely re-fitted) and Class-Rooms are now open.

ASSAYS, ANALYSES and Investigations connected with PATENTS conducted.

Pupils received for Class and Private Study. Special facilities are offered to persons preparing for GOVERNMENT EXAMINATIONS.

Classes are now forming for Practical Study in CHEMISTRY, STEAM, and PHYSICS.

For particulars, apply to Professor E. V. GARDNER, F.A.S. M.S.A. at the Institution.

South London School of Chemistry and Pharmacy. Director—Dr. JOHN MUTER, F.C.S.

Hours of Lecture for Session 1872-73:—

Chemistry (Inorganic)	10 a.m.	Materia Medica	4 p.m.
" (Organic)	2 p.m.	Pharmacy	2 p.m.
Botany (Structural)	11 a.m.	Classics (Junior)	9 a.m.
" (Systematic)	3 p.m.	" (Senior)	4 p.m.

Laboratory open for Practical Chemistry from 10 till 4.

This School affords the most eligible opportunities for obtaining at once a rapid, complete, and practical knowledge of the subjects taught. All the fees are perpetual until the examination in view is passed without reference to time. Country Students visiting London are placed in Lodgings registered by the Secretary, where no impositions are permitted to be practised, and where the prices are all on a fixed moderate scale. For terms, apply to the Director, or to

W. BAXTER, Secretary.

231 and 285, Kennington Road, S.E.

THE LIVERPOOL COLLEGE OF CHEMISTRY, 96, DUKE STREET, LIVERPOOL. Specially Devoted to the Study of CHEMISTRY, TECHNOLOGY and ASSAYING.

Laboratories open throughout the Year.

MARTIN MURPHY, F.C.S., &c., Principal (Successor to the late Dr. SHERIDAN MURPHY).

A Special Laboratory is devoted to Commercial Analyses of every description, and to Mineral Assays. Manufacturers' and Smelters' Analyses and Assays undertaken on Contract.

Patentees and Inventors Advised and Assisted. Works and Mines Inspected. The Erection of Manufacturers' Plant Supervised, &c. Terms and Fees VERY MODERATE.

Further Particulars and Full Prospectus on application to The Principal, MARTIN MURPHY, F.C.S. &c.

For Sale.—A Set of Metallic Elements in Stopped Bottles, appropriately labelled. Price, £6. May be seen at the CHEMICAL NEWS Office, Boy Court, Ludgate Hill, E.C.

ETHER SULPHURIC,

FOR REFRIGERATORS, ANÆSTHESIA, &c.,

AND

PURE FOR MEDICINAL USES.

MANUFACTURED BY **DUNN & COMPY.,**

MANUFACTURING CHEMISTS.

AT THEIR STIRLING CHEMICAL WORKS

STRATFORD.

All Letters to be addressed to

10, PRINCES SQUARE, FINSBURY.

FOOT, BARRET, AND TEMPLE,
BATTERSEA.

ACETIC & NITRIC ACIDS.

MANUFACTURERS OF
HYDRATE OF CHLORAL.

LIEBIG COMPANY'S EXTRACT of MEAT.

—None genuine without the Inventor's facsimile in blue being on the Trade-mark label and outer cover. Pure condensed Essence of Beef Tea, excellent economic flavouring stock for soups, sauces, and made dishes.

"Food for the nerves." (Liebig).

Water-glass, or Soluble Silicates of Soda
and Potash, in large or small quantities, and either solid or in solution, at **ROBERT RUMNEY'S** Ardwick Chemical Works Manchester

**FLETCHER'S NEW UNIVERSAL
FURNACE (GAS)**

For MUFFLES, CRUCIBLES, LADLES, and general purposes; requiring neither blast nor attention, and working at any required temperature with certainty.

Small sizes for Laboratory work. Large sizes for brass and iron castings, reducing photo. waste, photo. enamelling, assaying, and all purposes where exact results are required without constant attention. More than fifteen hundred of these furnaces are now in use. Drawings and descriptions free by post.

THOMAS FLETCHER, F.C.S.,
15, BOLD STREET, WARRINGTON.

ESTABLISHED 1798.

ROBERT DAGLISH & CO.,
BOILER MAKERS, ENGINEERS, AND
MILL-WRIGHTS,
BRASS AND IRONFOUNDERS,
ST. HELEN'S FOUNDRY, LANCASHIRE.

Makers of every description of Chemical, Colliery, Copper Ore, Gold Mining, and Glass Machinery, including Crown, German Sheet, and Plate Glass Plant, as supplied to some of the largest Firms in England, Ireland, Scotland, and Wales.

Makers of the latest Improved Revolving Black Ash Furnace, with Siemens's Patent Gas Arrangement, and as used in the Manufacture of Soda.

Improved Valveless Air Engines, and Pumps for Acid Forcing, Air Agitators, Compressors for Collieries, and Weldon's Patent Chlorine Process.

Caustic, Chlorate, Decomposing, and Oxalic Pans.

Gas Producers for Heating Furnaces.

Pyrites Burners for Irish, Norwegian, and Spanish Ores.

Retorts, Acid, Gas, Nitre, Nitric Acid, and Vitriol Refining.

Improved Steam Superheaters for Resin Refining, &c.

Improved Steam Sulphur Pans.

Photographs, and other information, supplied on receipt of Orders.

Chloride of Calcium (Purified Muriate of Lime),
total insoluble impurities under $\frac{1}{4}$ per cent.

CHLORIDE OF BARIUM (Muriate of Baryta), free from Iron and Lead, total impurities, water excepted, under $\frac{1}{4}$ per cent

GASKELL, DEACON, & CO.,

ALKALI MANUFACTURERS WIDNES, LANCASHIRE.

Silicates of Soda and Potash in the state of
Soluble glass, or in CONCENTRATED SOLUTION of first quality, suited for the manufacture of Soap and other purposes, supplied on best terms by **W. GOSSAGE and Sons, Widnes Soapery, Warrington.**

London Agents, **CLARKE and COSTE**, 19 and 20, Water Lane, Tower Street, E.C., who hold stock ready for delivery.

SCIENTIFIC PRESENTS.—Collections to illustrate "Lyell's Elements of Geology," and facilitate the important study of Mineralogy and Geology, can be had at 2s. 5s. 10s. 20s. 50s. to 500 guineas; also single specimens of Minerals, Rocks, Fossils and Recent Shells. Geological Maps, Hammers, all the recent publications, &c., of **J. TENNANT, Mineralogist to Her Majesty**, 149, Strand.—Private Instruction is given in Geology and Mineralogy by **Mr. Tennant, F.R.G.S.**, at his residence, 149, Strand, W.C.

PRACTICAL CHEMISTRY.

Laboratory, 60, Gower Street, Bedford Square, W.C.

Mr. Henry Matthews, F.C.S., is prepared to give Instruction in all branches of **PRACTICAL CHEMISTRY**, particularly in its application to **MEDICINE, AGRICULTURE, and COMMERCE.**

The Laboratory is open daily, except Saturday, from ten to five o'clock; on Saturday, from ten till one o'clock.

Mr. Matthews is also prepared to undertake **ANALYSES** of every description.

For Particulars and Prospectuses, apply to **Mr. Henry Matthews** the Laboratory, 60, Gower Street, Bedford Square, W.C.

THE CHEMICAL NEWS.

VOL. XXVII., NO. 771

12 JUL 73

CURIOUS REACTION OF BENZOIC, SALICYLIC, AND HIPPURIC ACIDS.

By T. L. PHIPSON, Ph.D., F.C.S.

When benzoic acid and glucose, in the proportions of about 3 equivs. of the former to 1 equiv. of the latter, are mixed with a large excess of monohydrated sulphuric acid, and the mixture is slightly warmed, a fine blood-red colour is developed, very similar to that produced when salicin or willow-bark are touched with concentrated sulphuric acid. After a while the mixture becomes brown, and then blackens. Benzoic acid alone does not produce this reaction. It matters little whether the glucose is artificial or natural.

Salicylic acid, with glucose, treated in the same manner, presents the same reaction in a still more decided manner.

Hippuric acid, with glucose and sulphuric acid, gives first a clear brown mixture, in which also the blood-red colour soon develops itself; then the whole mass becomes black, and evolves a large quantity of an odourless and colourless gas. This gas is not absorbed by water nor by potash, and is inflammable, burning with a blue flame: I conclude that it is chiefly oxide of carbon. As the reaction continues from this time, after the source of heat is withdrawn, the mixture soon becomes very hot, and then sulphurous acid is given off also.

PRELIMINARY NOTE ON THE REDUCTION OF SULPHURIC ACID BY HYDROGEN.

By G. J. WARNER, F.C.S.

For several years past I have used a method to avoid percussive ebullition in distillation, which I have found very satisfactory, viz., that of passing through the liquid in the retort a slow current of some inert gas which is easy of preparation. Dry air, carbonic acid, and hydrogen are those most generally applicable.

I had frequently distilled sulphuric acid in a current of air which had been previously dried over calcium chloride, but on using hydrogen I find that a large quantity of sulphurous acid is always evolved.

This reaction appears to commence at about 160° C., and the quantity of sulphurous acid formed increases with the temperature, but at no point was the decomposition complete. At temperatures near the boiling-point sulphuric acid always distilled over unchanged.

Fearing that the reduction might arise from the presence of hydrogen sulphide in the hydrogen, produced by sulphurous acid in the acid used for its preparation, I passed the gas first through a solution of lead acetate, and then over calcium chloride, when the same reaction ensued, although the lead solution was not blackened. Every precaution was taken to avoid the contact of cork or india-rubber with the acid vapour, the hydrogen being passed through a glass tube ground into the neck of the retort.

In some measure to confirm this reaction, I heated (1) redistilled sulphuric acid in an atmosphere of hydrogen, in a sealed tube, for twelve hours, at a temperature of 205° C.: when broken, a quantity of sulphurous acid was found in the tube in the gaseous state. (2). Two similar tubes, containing the same acid in air, heated at the same time to 205° C., contained, when opened, no sulphurous acid. (3). A sealed tube, containing hydro-potassic sul-

phate fused and filled with hydrogen, was likewise heated to 205° C. for twelve hours: a quantity of sulphurous acid was formed. (4). Two similar tubes, containing the same salt in "air," contained no sulphurous acid. (5). With dried ferrous sulphate, similarly treated, no sulphurous acid was produced at that temperature.

I intend to pursue this subject further, and to investigate the effect of nascent hydrogen on sulphuric acid of various densities, at the temperatures of their boiling-points.

This will, I expect, afford an explanation of the fact that sulphuric acid, even containing a considerable proportion of water, yields, when heated to the boiling-point with zinc, not hydrogen, but sulphurous acid.

NOTE ON THE NESSLER TEST.

By J. ALFRED WANKLYN.

In the course of the various controversies relating to the water process frequent mention has been made of the time required for the development of the Nessler colour. According to some experimenters, a few minutes suffice for the full colouration; according to others, half an hour or more is necessary.

These differences have their origin in differences in the quality of the Nessler reagent. I have known two Nessler reagents which, although in the course of hours giving the same depths of colour with the same quantity of ammonia, required very different times for the production of the colouration. One sample of Nessler reagent gives its maximum of colour almost immediately, and another sample takes a quarter of an hour or an hour for full development.

To a great extent, these differences depend upon whether or not a sufficient quantity of solution of corrosive sublimate has been added to the finished Nessler reagents. Whether the *Nesslerising* takes a couple of minutes, or whether it takes an hour, is a matter of vital importance to those persons who are working the ammonia process of water analysis; and since the employment of the ammonia process has become almost universal, I have deemed it to be worth while to direct attention to the necessity of a careful preparation of the Nessler reagent. I have, moreover, made arrangements with Messrs. Townson and Mercer for the supply of *quick Nessler* reagent at the rate of twenty shillings per litre. Those chemists who do not feel disposed to take the trouble of making the reagent themselves have now the opportunity of buying it

NOTES ON THE ANALYSIS OF ANIMAL CHARCOAL.

By JAMES M. MILNE, Ph.D.

Two papers on the above subject have recently appeared in the *CHEMICAL NEWS*, viz., one by Mr. T. L. Paterson (vol. xxvii., p. 111), and a short review of the same by Mr. A. S. Wilson (vol. xxvii., p. 225). A somewhat lengthy discussion on the same subject has also been carried on, in the pages of the "*Greenock Sugar Trade Review*," between Mr. Paterson and Mr. Murphy, of Liverpool, the practical results of which seem somewhat small when compared with the amount of noise made. Some of the statements made are, to say the least of it, rather novel; but it is a pity that a scientific discussion should be allowed to degenerate into mere personal wrangling, not to speak of doggerel rhymes.

With the view of satisfying myself as to the accuracy of some of the points in dispute, I have recently made a considerable number of experiments. These have been more especially directed to the determination of the moisture in samples of new char, and the presence of organic matter soluble in water.

In one of his replies to Mr. Paterson, Mr. Murphy makes the somewhat startling announcement that water with which new char has been treated is *strongly alkaline*, and will therefore dissolve appreciable quantities of organic matter from a paper filter. He thus accounts for the soluble organic matter found by Mr. Paterson in his experiments. I must confess that I, for one, have yet to learn that the water from new char is *strongly alkaline*, much more that it will dissolve filter-paper. In order to set aside all doubt on the subject, however, the following experiment was made:—5 grms. of a sample of new char were treated with water, and the liquid filtered without the use of paper, the neck of the funnel being stopped with recently-ignited asbestos. The filtrate, which was quite colourless, and only very feebly alkaline, was carefully evaporated to dryness in a weighed platinum basin; the residue dried at 130° C., weighed, and cautiously ignited. The contents of the basin blackened quite perceptibly; and on the ignition being completed, and the capsule weighed, the loss was found to be 0.112 per cent.—a result corresponding very closely with that given by Mr. Paterson in his paper.

Although the moisture in samples of old or used char can be correctly determined at 212° F., it is well known that this temperature is quite inadequate for the expulsion of the *whole* of the water from new char. In his instructions for the analysis of bone-black, Fresenius gives 160° C., to 180° C. (320° F. to 356° F.) as the temperature at which the moisture should be estimated. A few years ago Dr. Wallace, in a paper on "Animal Charcoal," gave it as his opinion that a temperature of not less than 350° F. was necessary. Mr. Paterson, however, considers 350° F. much too high, and sufficient to destroy a portion of the organic matter. He considers that five hours in the water-bath at 212° F. is all that is necessary, and asserts that char, during the process of pounding, always loses water. Now, while it is quite possible that long-continued grinding in a warm atmosphere may have that effect, it is difficult to understand how a porous substance like charcoal, which retains water somewhat persistently, should lose some of it, during the short time necessary for reducing it to powder. On the contrary, we should rather expect a slight increase. That this is really the case, the results of Mr. Wilson's experiments, as well as my own, seem to demonstrate. The following experiments were made with reference to this part of the subject:—

A.—(1). A sample of new char was taken, and one-half reduced to powder; both were placed in tightly-corked bottles: 2 grms. of each were weighed out and kept in the water-bath, under precisely similar conditions. The loss of weight was as follows:—

	Unground.	Ground.
After 1 hour ..	4.67 per cent.	4.92 per cent.
" 3 hours ..	4.85 "	5.09 "
" 5 " "	there was no further loss in either case.	

(2). 1.2802 grms. of the same sample was heated in an ordinary air-bath, at different temperatures, as under:—

	Unground.
At 350° F. for 15 minutes the loss was 6.11 per cent.	
" 400° " 10 m. longer "	6.78 "
" 450° " 10 " "	6.86 "
" 500° " 10 " "	7.36 "

(3). 2 grms. of the sample were placed in a platinum-boat, and introduced into a glass tube about 9 inches long. The tube was then placed in an air-bath, made for the purpose, and one end attached to an apparatus for drying the air previous to entering the tube. To the other end a weighed chloride of calcium tube was attached, and this again was placed in communication with one arm of a Staedler's aspirator, by means of which a uniform and well-regulated current of dry air could always be obtained. The air-bath was heated by a small Bunsen, the temperature being registered by a thermometer passed

through the Hd. For temperatures not over 350° F. a glass tube of this form  is useful, the thermometer being passed through a cork, but for higher temperatures a plain tube is to be preferred.

A great number of experiments were made with this apparatus, in order to determine the water by direct weighing, some of the results of which are given below.

Two grms. heated in the air-current:—

	Unground.	Ground.
At 350° F. for 15 minutes gave 6.50 per cent.		6.52 per cent.
" 450° " 10 m. longer "	7.01 "	7.07 "
" 500° " 10 " "	7.17 "	7.19 "

B.—(1). Another sample of new char (*foreign*) was subjected to the same mode of treatment.

Two grms. of the unground sample placed in the water-bath lost:—

In 1 hour ..	3.23 per cent.
" 2 hours ..	3.29 "
" 4 " "	3.34 "
" 5 " "	3.38 "

After 5 hours there was no further loss.

(2). The same quantity was placed in the air-bath.

At 250° F. for 15 minutes the loss was 3.92 per cent.	
" 350° " 30 " "	4.51 "
" 450° " 30 " "	5.01 "
" 500° " 30 " "	5.22 "

	Per cent.
2 grms. heated directly to 500° F. for 20 minutes lost 5.43	
2 " " 500° " 20 " "	5.08
2 " " 500° " 10 m. longer "	5.28

(3). Two grms. treated in air-current:—

At 250° F. for 15 minutes gave 4.17 per cent.	
" 350° " 15 m. longer "	4.62 "
" 525° " 5 " "	5.32 "

Two grms.—

At 350° F. for 15 minutes gave 4.61 per cent.	
" 450° " 10 m. longer "	4.81 "
" 500° " 5 " "	4.92 "

Two grms.—

At 450° F. for 30 minutes gave 5.03 per cent.

Two grms.—

At 450° F. for 20 minutes gave 5.24 per cent.	
" 500° " 15 m. longer "	5.29 "

Two grms. were taken as before, but in this case the loss of weight was also found by weighing the residue in the boat, which was placed in a closed tube.

	Gain in CaCl ₂ Tube.	Loss from Residue.
At 500° F. for 10 min.	5.40 per cent.	6.63 per cent.
" 500° " 15 " "	5.47 "	—
" 500° " 20 " "	5.55 "	6.98 "
" 525° " 5 m. longer "	5.65 "	7.22 "

Two grms.—

At 500° F. for 20 min.	5.35 "	6.03 "
" 500° " 30 " "	5.37 "	6.21 "

From an examination of the above results we are justified in concluding:—

1. That the water in a sample of new char is sensibly *increased* by the process of pounding, instead of being diminished.
2. That a temperature of 212° F. is quite inadequate for the determination of the water in such samples.
3. That there is a *loss* on heating in the air-bath up to 500° F., and that, if heated in the air-current, there is a *gain* in the CaCl₂ tube up to that temperature, showing that even at 350° F. the water is not completely expelled.

The determination of the water by *direct* weighing is, of course, to be preferred to the ordinary air-bath, which at the higher temperatures usually gives too high results. The difference between the gain in the CaCl_2 tube and the loss from the residual char shows that the loss of weight is not entirely water. I would recommend heating in the air-current for, say, 30 minutes, as giving reliable results.

Chemical Laboratory,
107, Bath Street, Glasgow.

ON THE ACTION OF WATER ON LEAD.

By Sir ROBERT CHRISTISON, Bart.

THE most general results of the author's former inquiries are—1. That the purest waters act the most powerfully on lead, corroding it, and forming a carbonate of peculiar and uniform composition. 2. That all salts impede this action, and may prevent it altogether, some of them when in extremely minute proportions. 3. That the proportion of each salt required to prevent action is nearly in the inverse ratio of the solubility of the compound which its acid forms with the oxide of lead.

The effect of certain inorganic and organic ingredients of water in modifying the preservative power of the salts the author did not investigate. This has been made the subject of numerous inquiries and observations by others, chiefly, however, of a desultory nature, some of them much too succinctly described, and some, also, of questionable accuracy.

It has been denied that water acts by reason and in the ratio of its purity; and it has even been alleged that distilled water itself does not act if really quite pure. The author has, however, invariably found the reverse to be the case, and can assign no other explanation of these statements, except some error in manipulation. For example, a very pure spring water was sent to him from the south of England, with the assurance that it had been found incapable of attacking lead; but, on making trial of it, he found it to act with an energy not inferior to that of distilled water.

It has also been stated that ordinary distilled water is apt to contain a trace of nitric or nitrous acid, from nitrates incidentally present in the water subjected to distillation; and that such water, if distilled after the addition of a little potash to fix the acid thoroughly, yields a distillate which has no action upon lead. But when the author prepared distilled water in this way, with great care to prevent the access of impurities from other sources, the only result was that the action was even stronger than that of the ordinary distilled water of the laboratory, and greater, indeed, than he had ever before observed.

An interesting statement has been made by Dr. Nevins, to the effect that some salts appear to allow of a certain action going on when they are present in water largely, although their influence when they exist in very small quantities is to act as preventives. This result the author has sometimes obtained, and has found the action such as might prove dangerous. But its limit requires to be defined; and there is reason to suppose that the proportion required to *permit* action will be found to be greater than is ever likely to occur in the instance of waters applicable to household use.

It has also been said, but in general terms and without experimental proof, that the presence of carbonate of soda, even in a hard water, takes away the preventive influence of the other salts, and enables the water to dissolve lead. There appears to be some foundation for this statement; but here, too, it is necessary to fix what is the limit to such influence before its importance can be valued. Moreover, as bicarbonate of soda appears to have no such effect, and this is the usual form of the car-

bonate in natural waters, the practical importance of the fact is inconsiderable.

The corrosive action of water upon lead has often been confounded with other causes of corrosion, and the water has borne the blame. Thus the true action has been confounded with the corrosive action of potent agents accidentally coming in contact with the metal in the presence of water, as, for example, when a lead pipe has been led through fresh mortar, which is frequently or permanently kept moist, or when lumps of fresh mortar have been allowed to fall upon the bottom of a lead cistern.

The true or simple action of water has not unfrequently been confounded also with the effects of galvanic action. Thus, if a lead pipe or cistern be soldered with pewter solder and not with lead, erosion takes place near the line of junction of the solder with the lead. The presence of bars of other metals crossing lead, or bits of them lying on it, will also develop the same action; and some facts seem to point to the same property being possessed in a minor degree by some stony and earthy substances. This observation may explain the local erosion sometimes observed in cisterns containing hard water; since, if galvanic action be excited, it will be increased by the fact of saline matter existing more largely in these waters than in soft or comparatively pure water.

Lastly, some observers have contradicted former statements, because under certain circumstances, which led them to anticipate no action, they nevertheless found lead in water, but only in extremely minute and unimportant proportion. The test for lead, hydrosulphuric acid, when employed in the way now usually practised is so delicate as to detect that metal when dissolved in ten million parts of water, or even more. Facts, however, warrant the conclusion that the impregnation must amount to at least ten times this quantity before water can act inferiously on man, however long it may be used.—*Iron*.

ON THE ENERGIES OF THE IMPONDERABLES, WITH ESPECIAL REFERENCE TO THE MEASUREMENT AND UTILISATION OF THEM.*

By the Rev. ARTHUR RIGG, M.A.

(Continued from p. 7).

MEN need but watch the progress of science-truths for a few years, or read the development, stage by stage, of any branch of investigation, to be satisfied of this, that, with whatever pertinacity and show of reasoning any theory is propounded and established, it rapidly wanes. Astronomical and geological truths and facts, how often and again have they been satisfactorily (?) explained, and yet how soon and how rapidly has one explanation been so crushed out by another, that the first, which by its authors was applauded, is by the upholders of the second ridiculed.

The theories of the imponderables, with which we must occasionally deal or allude to, but with which we are in no degree further concerned, are, day by day, in a transition state. Like the cause of solar heat, or the rotation of the moon, they are a bloodless battle-field, on which, with our increasing love of talking and our decreasing love of working, words may war with words.

A triumphant victory to-day in science theory may be the prelude to an ignominious defeat of the same theory to-morrow. Subject, doubtless, to many dissentient views, the belief that he who propounds a theory, and uses theories solely as means or ways by which to convey ideas of how such and such facts may perhaps be brought about, and not as expressing a conviction that the way described is the actual plan in operation, he is the truly wise man. Those who allow themselves to dwell upon the conception

* The Cantor Lectures, delivered before the Society of Arts.

and the development of theories, who build theory upon theory, who sometimes pile Ossa upon Pelion, and sometimes Pelion upon Ossa, are not unlike those whom Milton describes—

"Who reasoned high
Of providence, foreknowledge, will, and fate,
Fixed fate, free will, foreknowledge absolute,
And found no end, in wandering mazes lost."

Thus it is that the decisions of one age and one day differ from those of another age and another day. Theories, we must remember, are but opinions; with opinions, as such, this course of lectures is not concerned. The facts of Nature, so far as they have yet been made apparent, or may be in process of being so, are our province. They change not. To those who have appealed to Nature direct, and brought from her exhaustless stores of knowledge some truths that men may utilise, is due the information which is to be brought before you.

The mode by which they have won this knowledge is exactly that pursued in our courts of law and equity, to arrive at the truth on one point, and on one point only. Look how long and tedious legal investigations seem, and yet in how few words the result is declared. Guilty or not guilty—Verdict for the plaintiff or verdict for the defendant. One or other of these very brief phrases records the conclusion or the judgment of many days of patient labours and searchings for truths.

To not less careful questioning by men in years past, as well as now current, we owe all we know of the energies, the measurement and utilisation of which is to be a feature in these lectures. That cross-questioning of the keenest and clearest kind has been essential may be inferred from the fact that these energies are so co-related—so mutually convertible—that they merge and change, Protean-like, one into the other so instantaneously that no one energy can be conveniently retained alone and in operation. They thus pass and interchange without (to our eyes) a signal from any magician's wand.

The transmutations of the imponderables are accomplished in a way that would have gladdened the eyes of the most profound alchemist, could he have seen as great transmutations in some of the material things in which he worked. For example, whenever energy is lost by resistance, heat is produced, *i.e.*, when the resistance is perfect and complete, admitting of no intermediate state; *e.g.*, if a wheel in machinery does not move easily, the consequence is heat, manifested on the shaft.

If, however, that energy can be converted into an intermediate state, then this state may be assumed—much as light from gas is an intermediate state between chemical affinity and heat. Do what we may, that from which energy results can neither be created nor destroyed.

In the case of blows by impact, as in the tongue of a bell, or the hammer on an anvil, or a clock, or a piano, or on a drum-head, or on a gong, then, whilst doubtless some part of this checked energy is converted into heat, yet a large portion is spent in the production of vibrations in matter, appreciable to our senses, and suggestive of vibrations in molecules, which our senses, aided by physical appliances, have not yet made visible, but which chemical changes, and what to the minds of science theorists of the present day is conclusive evidence, seem to point as similar vibrations in the invisible molecules and atoms of which it is assumed that bodies consist.

These remarks may suffice to explain that whilst to speak of estimating an "energy" is easy, yet to estimate that "energy" is an employment which tasks the keenest and most watchful faculties of the human mind, as well as claiming from human hands the production of some of their most exquisite and refined work.

The difficulty of the task results not so much from a solution of the simple problem which the words "estimate that energy" convey, as from the incompetence alluded to of isolating and continuing the special energy and noting its operation. For no one of nature's energies,

be they ponderable or imponderable, is alone. Solitariness in the unseen, as well as in the seen, is no part of nature's plans.

Faraday seemed to have realised this view in great intensity when he wrote—"If, as I believe, dualities are essential to the forces, are always equal, are mutually dependent, that one cannot appear or exist without the other: the proof of this would lead to many consequences of high importance to the philosophy of force generally."*

This interlacing of energies,—this co-relation, as it is called, of physical forces,—whilst it knits in harmonious union energies which are nominally distinct, baffles the investigator who wishes to assign to each its share in any specific work. For example, the energy of gravity operates everywhere, and our fundamental principle in hydraulics, that fluids press equally in all directions, may be granted as a postulate. The experiments by which it can be confirmed may be and is very clearly described, but no one has ever made or can make them. Gravity never ceases to impress upon fluids a downward tendency, and so prevents an equality of pressures in all directions being established.

It may be in the interest of the Moslem faith to assert that, without visible means, Mahomet's coffin rests between earth and heaven; but, assuming the truth of the tradition, or of the fact (whichever it be), we know well that gravity operates in all its wonted intensity, and that the coffin is held there (if held at all) by the introduction of some counteracting energy, as that of magnetism.

The energy of electricity is ever passing into heat—that of heat into electricity or light. Electricity, again, appears to assume the form of vitality; and then, again, it totally fails to fulfil the vital conditions. In some animals the exhaustion of their muscular energy is consequent upon the exhaustion of their vital energy, and no electrical appliance can restore the vital energy, even though it seems to restore the muscular. Take affinity. This passes, by means unknown to us, into electricity and heat.

There is also this peculiarity amongst these energies. The work of one energy, estimated by any means known to us, gives no indication of the work of some other energy, resident or potential, in the same matter.

For example, the estimation of a drop of water by gravity standards—to speak of it as weighing so many grains—gives no indication whatever of its ability to promote affinities, to absorb and convey heat, to decompose light. And if even all these were known, there would still be no indication that upon an electrical standard of measurement its destructive effects are equal to that of a flash of lightning.

The only energies that may be said to be non-interchangeable are those of gravity and vitality. The former is enduring, the latter fleeting. The character of the one is persistence and constancy; that of the other, change and variety. Gravity may be said to be quietly resident in matter; vitality shows its presence by growth or motion.

Gravity is an energy pervading all nature, as intense in grains of sand as in the mountain; in a drop of water as in the river or the ocean. Disregarding alike the vitality of the plant or the animal—for gravity treats them as though they were as inert, indifferent, and unconscious of its presence as the soil of the garden, or the mineral under the earth—thus this energy, which is to occupy our chief consideration in the next lecture, is alone, and yet we shall find how that it has been left for recent times to tabulate its measure, to report and utilise, under the guidance of ordinary arithmetical and mathematical rules, the scientific and social consequences of the measure so established.

The other energy, that of vitality, which is to occupy

* *Proc. Roy. Inst.* for 1854. 6.

our attention in a future lecture, can hardly as yet be said to have been measured. The time, however, is very near when the hope will be realised; that the energy of vitality—the mechanical, the statical, dynamical, and absolute energy, of course, is meant—may be reduced to as exact a science as those of light, heat, and electricity have recently been.

All who have questioned Nature are well aware how simply and truthfully she replies. It must, however, be steadily borne in mind that this truthfulness applies to the question and answer in their mutual relations. If the question be so put that Dame Nature has to answer in respect to the combination of two elements, and so is called upon to give a reply which is in truth the aggregate of the two, she does so. It behoves the questioner to frame his question with the utmost care, in order to eliminate what is extraneous to his purpose. All must have observed how difficult it is to frame a question which cannot be mis-read, or admit of a reply evidently based upon a view which the questioner never contemplated. For example, if the question relates to gravity, caution is needed to exclude the buoyancy and even viscosity of the air, and the centrifugal effects of the earth's rotation.

If it relate to electricity, caution is needed to exclude the most infinitesimal alloy of a metal—even a metal itself.

If it relate to vitality, caution is needed to exclude the effects of temporary exhilaration or prostration.

If it relate to affinity, caution is needed to exclude the complication of phenomena by variations in gaseous pressure or atmospheric temperature.

If it relate to heat, caution is needed to exclude peculiarly constituted substances, in their unknown and varying effects on heat from their atomic or rather molecular condition.

Although, for purposes of classification and the general distinction of the phenomena, the energies found in nature are arranged under the general energies which are prefixed to the respective lectures of this course, yet it must be borne in mind that these are verbal rather than emphatically actual distinctions. They are merely the terms recognised at the present day, and in a few years may be dismissed. The convertibility of energy just now alluded to is a phrase which conveys a clear meaning, but this convertibility is a process that cannot be followed. At one time in the science world a general principle seems to have been established in relation to it; again and again the hope fades, the principle is on no secure basis, whilst the convertibility is ever active. It may not inappropriately be asked which energy is the source of the others—which, in fact, seems to have the highest claim to be classed as *the one*. Doubtless, as a question of sequence, in time gravity must claim the first place, but, so far as our powers of utilising the energies of the imponderables are concerned, we are not able to appeal very hopefully to gravity. We cannot obtain the other energies from it. Gravity refuses to be converted; its political principles are of the type which permits no change. Nature's No. 1 must be gravity; man's No. 1 affinity. For example, oxygen and hydrogen manifest their affinities in obedience to some inexplicable law. They enter into what is called combination, and in so doing manifest one form of energy to which the name of the "energy of affinity" is given. But in the transition state—in the act of obeying the very imperfectly known laws of affinity—another energy of a different name and character appears, viz., heat. Evidence of the power of this energy—heat—is furnished to tests very different to those which may be applied to the energy of affinity. The heat is presented to the thermo-electric pile, and that a great change in the mode of its energy has taken place is obvious from the results it produces at a distance; to this new form of energy we give the name of electricity. By a species of magic, electricity has called forth an energy to which is given the name of magnetism. Suitable circumstances

being presented to this new energy, there is a machine propelled and capable of doing mechanical work. We now call it mechanical energy.

Thus, by change superposed on change, the energy of an imponderable has been converted into that energy of the ponderable to which we are indebted for all, or nearly all, of arts, manufactures, and commerce.

The two imponderable energies into which chemical affinity cannot be converted are vitality and gravity. These two may, as we shall hereafter find, assume the form of the others—the others cannot assume their forms—at least not in any plain and honest sense. Except in these two physical energy is a visible reproduction of the invisible doings of chemical affinity.

Simple as this process of transformation may appear, and convenient and useful as the suddenness of the change may be, it cannot be denied that to the investigator it is perplexing. Men, however, labour on, each perhaps winning a little from the unknown, and adding it to the known. Thus, although "hills peep o'er hills, and Alps on Alps arise," yet men of varied resources and patient perseverance have won those invaluable treasures of measurement and utilisation from the imponderables and unseen which give the title to this course of Cantor Lectures.

Even Livingstone has not shown a more noble resolve "to conquer or to die" than have those to whom we are indebted for all we know touching the modes of measuring the energies of gravity, vitality, affinity, electricity, light, and heat.

As illustrations of the difficulties of the tasks before them, it may suffice, in this introductory stage, briefly to observe that:—

Galvanic currents may escape notice unless the intensity of terrestrial magnetism be neutralised.

Diamagnetism and the magneto-electric spark escape notice, unless a large number of galvanic cells or their equivalent is used.

What was called the "smell of electricity" led Schönbain to the discovery of "ozone," a remarkable product, and one whose energies are yet unknown, although being slowly but surely developed.

That a vibrating magnetising needle came to rest sooner in the neighbourhood of a copper plate, now called a damper, then when the plate was away, led to the discovery of the induction of electric currents by Faraday.

Opinions from telescopic appearances of the size of the stars led to an idea that their discs differed; the phenomenon has been found to be due to the diffraction of light.

The velocity of sound was calculated, making due allowance for the direction of the wind; in recent years it has been found that the heat developed by one particle of air striking another, must be taken into account.

(To be continued.)

Royal School of Mines.—At a meeting of the Council, held on Saturday, July 5, the following gentlemen received the diploma of Associate of the Royal School of Mines:—Mining and Metallurgical Division—E. Jackson J. A. Griffiths, C. Law. Mining Division—A. G. Phillips. Metallurgical Division—J. W. Westmoreland, S. W. Davies, J. C. Jefferson, H. S. Bell. Geological Division—G. Smith. The following scholarships and prizes were awarded:—The two Royal scholarships of £15 each, for first year's students, to Mr. W. Carter and Mr. A. J. Meeze. For second year's students—His Royal Highness the Duke of Cornwall's scholarship of £30 for two years, to Mr. C. Lloyd Morgan; and the Royal scholarship of £25, to Mr. S. A. Hill. The Edward Forbes medal and prize of books, for natural history, to Mr. G. Smith. The De la Beche medal and prize of books, for mining, to Mr. Edgar Jackson. The Murchison medal and prize of books, for geology, to Mr. C. Lloyd Morgan.

CORRESPONDENCE.

ON A SYSTEMATIC MINERALOGICAL
NOMENCLATURE.*To the Editor of the Chemical News.*

SIR,—As I see by your report last week of the meeting of the Chemical Society that Mr. Hannay has called attention to a new system of mineralogical nomenclature, I sincerely hope that this most important subject will not be allowed to fall to the ground until something has been done. No person will deny that the state of hopeless confusion into which the method of naming minerals has fallen is very injurious to the advance of the science, and there is nothing which would do more good to the science of mineralogy than the introduction of a real systematic method of naming the substances composing the crust of the earth. The present state of affairs makes a complete knowledge of mineralogy next to impossible, and the difficulty which beginners experience in gaining a knowledge of the properties and position of each mineral in relation to others (having no systematic name to guide them) is very great indeed. There has been an immense amount of work done in mineralogy, both in the chemical and physical constitution of the minerals; and this great body of work just requires one addition to bind together the scattered forces, and that addition is a systematic nomenclature. As chemists are by far the most influential body connected with this subject, I hope to see them take the matter up, and, by introducing a new system, set mineralogy on its feet.—I am, &c.,

R. W. EMERSON MCIVOR.

Glasgow, July 1, 1873.

ON BUTTER.

To the Editor of the Chemical News.

SIR,—I was much pleased to find in the CHEMICAL NEWS (vol. xxviii., p. 1) a paper "On Butter," by Dr. Brown. May I suggest to you the great benefit to myself and others if you would continue such valuable papers? The Adulteration Act now in use would justify surely such articles, and would enable chemists in the provinces to see the means used for detection of adulterations by gentlemen whose skill as analysts is above any doubt. I am not aware of any work on adulterations except Dr. Hassall's, and that I think is much too prolix as a handbook, although very excellent in its way.—I am, &c.,

J. B.

ON BUTTER.

To the Editor of the Chemical News.

SIR,—The extraordinary paper which Dr. Campbell Brown publishes in the last number of the CHEMICAL NEWS calls for a few words of comment. Dr. Brown, who is a Doctor of Science of the London University, appears not to know that butter resembles suet, tallow, dripping, and lard by containing, as they do, stearin, olein, and palmitin; and that it differs from them only by containing these fats in different proportions, and by containing very small quantities of butyric, &c.

His notion of looking for the milk globules in butter is very amusing, especially when it is borne in mind that butter is frequently raised to its melting-point either by accident or by design, and, according to good authority, is none the worse for the process.

The analytical operations which he recommends for the purpose of detecting adulteration of butter with foreign fats appear to me to be utterly delusive; they are on a par with the chemistry of the composition of butter.

Inasmuch as Dr. Brown occupies a responsible position,

being Public Analyst for Liverpool, Cheshire, and the Isle of Man, I have felt it my duty to make this protest against his methods of procedure.—I am, &c.,

J. ALFRED WANKLYN.

London, July 5, 1873.

NOTICES OF BOOKS.

Notes of a Course of Nineteen Lectures on Natural Philosophy. Delivered at Guy's Hospital during the session 1872-3. By G. F. RODWELL, F.R.A.S., F.C.S. London: J. and A. Churchill. 1873.

NOTES, summaries, or recapitulations are, when properly made and used, of great value to the student,—are, in fact, quite necessary if he has to pass through the ordeal of an examination. Nevertheless they are very dangerous and liable to much abuse by becoming elements of the machinery of cramming. Hence we open this book with a certain degree of suspicion, which is not diminished by the preface, wherein the omission of Acoustics and the comparatively slight treatment of Light is explained by the fact that the Lectures "had special reference to the requirements of the Preliminary Scientific (M.B.) Examination of the University of London." An abstract of lectures delivered with this avowed object necessarily treads on the frontiers of cram, and no small amount of skill is necessary to keep them from stepping across.

On further examination of Mr. Rodwell's Notes, we find that this difficulty is very skilfully mastered, and a really sound and useful abstract of the subject is given; the short propositions are by no means stated in a form that would serve to mechanically pack the memory with a series of mere answers to examiners' questions. Considering the small space into which the subjects are condensed, there is a very fair amount of logical sequence binding together the propositions, which for the most part are stated rationally rather than dogmatically. Anything like complete demonstration is, of course, impossible in the space of such notes, nor could it have been attempted in the full extension of merely nineteen lectures required to cover the subjects of the Statics and Dynamics of Solids, of Hydrostatics, Hydrodynamics, Pneumatics, Light, Heat, Magnetism, and Electricity. Thus limited, there was no need of the apology in the preface for subjects omitted. The apology should rather have been for the excessive quantity which the compulsory limitations of the teacher's time has forced him to include in so short a course.

This work displays a defect which is common to most of our modern elementary treatises, one which appears to be growing at a rate which threatens to seriously damage the educational value of physical science. We refer to the statement of hypotheses in such a manner that the pupil is likely to accept them as actual facts. This is especially displayed in the summary of the subject of heat. The following is an example:—"Since all matter possesses a certain amount of molecular motion, and no two molecules are in contact, it follows that all molecules possess a certain amount of potential energy, and that the acts of heating and cooling (addition and subtraction of molecular motion), may be expressed respectively as the increasing and the lessening of molecular potential energy, considered in regard to its amount at the time of such addition or subtraction."

Here, as in other propositions, the existence of molecules, of inter-molecular spaces, and of molecular motion are described in the same positive and unqualified terms as expansion or contraction, solidity or fluidity, and there is nothing to indicate the vast difference between the actual and demonstrable facts, and the figments of philosophical imagination. Even if this conception of the discrete molecular constitution of matter were universally accepted, it would be absolutely necessary to sound intellectual

discipline that the student, at the very outset of his barest rudimentary studies, should be taught that these molecules separated by interspaces through which they swing with varying range of motion, are purely poetical conceptions to be clearly distinguished from the positive physical facts which they have been invented to explain. The use of the imagination in science, and in all other comprehensive efforts of the human mind is, perhaps, as necessary as the use of the senses and the reasoning faculties, but to escape the erection of a whole fabric of rotten fallacies we must clearly distinguish between the facts of observation, the conclusions of reasoning, and the creations of imagination.

As already intimated, these strictures are not applied solely or especially to the work of Mr. Rodwell, but refer to a generally growing vice of elementary works on physical science. We have thrown overboard "the imponderables," and no longer talk with flippant familiarity of electric magnetic fluids or of caloric, and therein have acted wisely, but our progress will become a mere oscillation if we erect mathematical idols on their pedestals, and worship them with equally unreasoning blindness.

Having uttered this protest, we may, for the rest, strongly recommend these Notes to all who need the intellectual refreshment of a well-arranged and carefully-written condensation of the leading facts and principles of the chief elements of Natural Philosophy.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Under this heading will be found an encyclopaedic list of chemical papers published abroad during the past week, with abstracts of all susceptible of advantageous abridgment. The two half-yearly volumes of the CHEMICAL NEWS, with their copious indices, will, therefore, be equivalent to an English edition of the "Jahresberichte."

NOTE. All degrees of temperature are Centigrade, unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances de l'Académie des Sciences, June 16, 1873.

Heat Liberated by the Combustion of Formic Acid.—M. Berthelot.—A thermo-chemical paper, bearing chiefly on the dispute pending between Favre and Silbermann on the one hand, and Thomsen on the other.

Alloys used for Gold Coinage.—E. Peligot.—Suggestion on a uniform international monetary standard.

Report on Investigations relating to Phylloxera vastatrix.—MM. Duclaux, Cornu, and L. Faucon.—An enquiry into the ravages of a vine-destroying insect, along with an analysis of the roots of the vine.

Researches on the Essence of Alangilan (*Unona odoratissima*).—This essence, lately introduced into the market, commands the price of 2500 francs per kilogram. It is extracted by distillation from the flower of a tree found in Jamaica. The specific gravity of the essence at 0° 15° is 0.980. A column of 5 c.m. in depth deflects a ray of polarised light 14° to the left. It distils over entirely between the temperatures of 160° and 300°, without leaving a carbonaceous residue behind. It is insoluble in water, partially soluble in alcohol, and entirely soluble in ether. After partial saponification with potassa it yields benzoic acid.

Contributions to the History of the Histological Constitution and the Chemical Function of the "Glairine" of Molitz.—A. Béchamp.—Glairine is a deposit obtained from the sulphur-springs of Molitz. It consists chiefly of gelatinous silica, and, like the micro-

zymas of chalk and other calcareous formations, is capable of exciting fermentation.

Determination of the Total Nitrogen contained in Manures.—H. Pellet.—The process consists in the addition of a large excess of inert organic matter (starch), and of soda-lime, to the nitrogenous organic matters containing nitrates. A combustion-tube is taken, 70 to 80 c.m. long, the end of which is charged with oxalate of lime and a small quantity of soda-lime: 1 to 2 grms. of the substance under analysis are weighed out, and well mixed in a mortar with 8 to 10 grms. of starch, free from nitrogen, and an equal weight of pulverised soda-lime. The success of the operation depends on the care with which this mixture is made. The tube is then filled up with soda-lime, and the combustion executed in the ordinary manner. The process is not found applicable to the assay of commercial nitrates, as the error would become too great.

Determination of Phosphoric Acid in Natural Phosphates and Manures.—H. Joulie.—A reply to Mène's criticism contained in the *Comptes Rendus* of June 9th. M. Joulie remarks that the process which Mène condemns as inexact is totally distinct from the one which he recommends. He points out that Chancel's process (bismuth), as its inventor admitted, is applicable only to substances containing little alumina and oxide of iron, and free from sulphates and chlorides—a state of affairs very rare in manures, and especially in superphosphates.

Method of Determining the Hæmoglobin in Blood.—M. Quinquaud.—The maximum volumes of oxygen absorbable by a given volume of any blood are proportional to the hæmoglobin which these bloods contain. For this purpose it is needful to know the weight of hæmoglobin corresponding to 1 c.c. of oxygen, and to determine exactly the quantity of oxygen which the blood in question retains when saturated: 100 c.c. of human blood contained 260 c.c. of oxygen, ox blood contained 240, and drake's blood 170. The amount of iron contained in 1000 grms. of blood, as determined by Pelouze, is—

Man	..	..	..	..	..	0.53	grm.
Ox	..	..	..	..	..	0.48	"
Drake	..	..	..	..	..	0.34	"

Hence the amount of hæmoglobin in 1000 grms. of blood is in—

Man	..	..	..	..	..	125	grms.
Ox	..	..	..	..	..	120	"
Drake	..	..	..	..	..	82	"

The numbers given by Preyer, as found by a spectroscopic method, are higher, but their relative proportions are the same.

Determination of the Mechanical Coefficients of Food.—A. Sansom.—A mechanico-physiological paper.

Experimental Researches on the Influence which Change of Barometric Pressure Exerts on Vital Phenomena.—P. Bert.—An interesting physiological investigation.

On Aniline Greens.—MM. Lauth and Baubigny.—The authors propose to replace the iodide of methyl, in the manufacture of certain aniline colours, by an ether with a mineral acid, a sulphate, hydrochlorate, nitrate or phosphate, or by the sulpho-conjugated acids of the alcoholic radicals. The best results have been obtained with nitrate of methyl in presence of an alkali or alkaline earth. The energetic action of this ether renders it practicable to operate at low temperatures, either in open or closed vessels.

Photochemic Researches on the Use of Gases, &c.—M. Merget.

Researches on Electricity Produced by Mechanical Action.—M. Joulin.

Polytechnisches Journal von Dr. E. M. Dingler,
No. 2, 1873.

On Pyrometrical Experiments.—A. Weinhold.

Remarks on the Decay of Rocks, and on the Increase of Volume accompanying Crystallisation.—F. Kuhlmann.

On an Alteration of Cast-Iron produced by the Action of a Mineral Water Rich in Sulphur.—E. Priwoznik.

Manufacture of Soda by Means of Bicarbonate of Baryta.—G. Lunge.

Processes for the Volumetric Determination of Carbonic Acid.—A. Houzeau.

Determination of the Amount of Acid in Fatty Oils.—M. Burstyn.

Berichte der Deutschen Chemischen Gesellschaft zu Berlin,
June 9, 1873.

Action of Ammonia and its Derivatives upon Ketones in Presence of Dehydrating Bodies.—MM. Engler and Heine.—The authors have investigated the action of ammonia upon acetophenon, and that of aniline upon acetone, both in presence of anhydrous phosphoric acid. In the former case they obtained a base to which they give the name acetophenonin, which shows few noteworthy reactions, and forms well-defined crystalline salts with acids.

Solubility of Saline Mixtures.—F. Rüdorff.—The author examines those cases where a decomposition is possible. He finds that when ammonia is determined by boiling a solution with caustic alkali, and receiving the ammoniacal fumes in standard sulphuric acid, the alkaline liquid bumps violently on boiling, especially if metallic salts are present. This may be avoided by heating, not by direct fire, but by blowing steam into the liquid.

On Trinitro-Naphthalins.—F. Beilstein and A. Kuhlberg.—The authors distinguish three trinitro-naphthalins: the modification α was obtained by d'Aguilar, on boiling α -dinitro-naphthalin (fusing at 211°) with fuming nitric acid. It crystallises from alcohol in saw-shaped leaflets, and fuses at 122° . β -trinitro-naphthalin is obtained by boiling β -dinitro-naphthalin for a few minutes with 5 parts fuming nitric acid and 5 parts strongest sulphuric acid. It is very readily soluble in alcohol, and melts at 213° . A third modification, γ -trinitro-naphthalin, is formed on treating α -dinitro-naphthalin with the above-mentioned mixture of sulphuric and nitric acids. It is precipitated with water, and re-crystallised several times from crude nitric acid. It forms splendid pale yellow leaflets. From fuming nitric acid it is deposited in brilliant four-sided tables. It melts at 147° .

Investigations on Isomerism in the Phenol Series.—H. E. Armstrong.

Natural System of the Chemical Elements.—H. Baumhauer.—The author prefers to arrange the atomic weights in the form of a spiral line on a plane surface, hydrogen being placed in the centre. He refers to his pamphlet, "The Relations between Atomic Weights and the Nature of the Chemical Elements," Brunswick, 1870. He points out that, on comparing the atomic weights with the specific gravities of the same bodies, both increase in the same direction in case of a homologous series of bodies. He traces relations of this kind in the following groups:—Sulphur, selenium, and tellurium; chlorine, bromine, and iodine; copper, silver, and mercury; magnesium, zinc, and cadmium; carbon, silicon, and tin; phosphorus, arsenic, antimony, and bismuth; glucinum and aluminium. A remarkable exception is found in the series of alkali metals,—the specific gravity of potassium being not greater, but smaller, than that of sodium.

Metallic Derivatives and Structural Formula of Cyanamid.—E. Mulder.—The author has previously

shown that hydantoin is not formed of the action of alcoholic ammonia upon bromacetyl urea. Neither is hydantoin formed on heating bromacetyl urea with alcohol in a sealed tube. Glucoluril is decomposed by hydrochloric acid into hydantoin and urea. The synthesis of glucoluril, therefore, may lead to that of hydantoin. By the reaction of bromacetyl urea and cyanamid the author obtained not glucoluril, but a sparingly soluble gelatinous body. If an aqueous solution of cyanamide is added to nitrate of silver a fine yellow precipitate is formed. Cyanamide is also precipitated by an ammoniacal solution of nitrate of silver, as the yellow precipitate is sparingly soluble in ammonia. It was found to be a silver substitute of cyanamid, CN_2Ag_2 . If cyanamid is CN_2H_2 , it would be more correctly named carbodiimid. Its change into guanidin becomes thus intelligible. An aqueous solution of urea, made alkaline with hydrate of soda, also gives a pale yellow precipitate with nitrate of silver. Silver carbodiimid has the following properties:—It is yellow, amorphous, insoluble in water, sparingly soluble in ammonia. It dissolves in dilute nitric acid, and is re-precipitated with ammonia. If potash is added to the nitric acid solution, silver carbodiimid is formed again, and can be boiled with an excess of potash without perceptible decomposition.

Action of Perchloride of Phosphorus upon Sulphacetic Acid.—R. Siemens.

Action of Sulphuric Acid upon Substituted Anilines.—H. E. Armstrong.—The author has studied the action of sulphuric acid upon ethylanilin and dimethylanilin. He announces as in progress the examination of the sulph-acids formed from the brom- and nitraniline.

The Relations between the Velocity of the Propagation of Sound in Gases and their Molecular Weights.—C. Bender.—The author concludes that these velocities in different gases are inversely as the square root of the molecular weights. Taking the so-called "dust-figures" of Kundt, he finds that the velocity of sound in the media in question is inversely proportional to them, and the square root of the densities directly proportional.

On Oxycymol and Thiocymol.—F. Roderburg.—The author seeks to compare the oxy- and thio-derivatives obtained from cymol with those obtained directly from camphor. The experiments show that in cymol-sulphon acid, and in the oxy- and thio-cymol obtained from it, the inorganic groups occupy the same position as do the oxygen and sulphur in the oxy- and thio-cymol prepared directly from camphor.

Respiration and the Inclosed Air of Sugar Beet-Root.—Arnold Heintz.—Sunlight induces chemical transformation in chlorophyll, the vegetable assimilative organ. The substances necessary to build up the body of the plant are produced from carbonic acid and water, oxygen being eliminated. The process may be thus generally expressed:—

If $x=6$ and $7=1$, the result is starch. If $x=6$ and $7=0$ we obtain glycose. The chemical intervention of atmospheric nitrogen in the matters of the living plant-cell is exclusively denominated respiration, and is diametrically opposed to the assimilatory process—the absorption of carbonic acid. Dutrochet rightly compares the respiring plant with insects and other cold-blooded animals, and Sachs likens oxygen to "the spring of a watch," whose elasticity sets all the parts in motion. In the growing plant the elimination of oxygen preponderates, but when the absorption of carbonic acid is interrupted the respiratory process becomes more prominent. As early as 1779 Ingenhauß discovered that roots, flowers, and fruits give out carbonic acid. Respiration, or slow combustion, can be well observed in case of the sugar beet-root, whilst its nutrition is suspended in the winter. The roots stored up for use go on respiring, and their sugar is decomposed.

It was found that a store of 1000 cwts. of roots lost, in two months, 10 cwts. of sugar. The air contained in the roots was found to be—

Revue Scientifique de la France et de l'Etranger, No. 50,
June 14, 1873.

Congress of German Naturalists and Physicians.
Session of 1872, at Leipzig. Chemical Section.

Michaelis described certain new compounds of phosphorus. He obtained $P_2S_2Br_4$ by acting upon bromine with triarsphide of phosphorus. By means of this body he prepared PS_2Br and $PSBr_3$, thus completing the group of the sulphobromides of phosphorus. He has also produced a compound of $PSBr_2$ with PBr_3 , and one of $PSBr_3$ with H_2O .

Rathke has formed the compound $CSCl_4$ by acting upon the bisulphide of carbon with chlorine. Another analogous body is produced during the reaction. The author describes the behaviour of these bodies with certain organic principles. Zincke described the compounds benzyl-isoxylol and benzyl-paraxylol.

Neubauer showed the presence of quercetin, quercitrin, malic, oxalic, tannic, and tartaric acids, and of inosite in the leaves of the vine.

Hlasiwetz made known the results of his researches on the protein bodies, undertaken conjointly with Habermann. Rithausen discovered some years ago, among the products of the decomposition of gluten, a new nitrogenous acid, which he named glutinamic, homologous to aspartic acid. The same acid has been obtained from legumin and other matters, so that it may be considered a no less constant result of the decomposition of proteic substances than leucin and tyrosin. Previously, however, glutinamic acid had only been obtained with proteic bodies of vegetable origin. Hlasiwetz and Habermann affirm that it may be obtained from animal proteic matters, and especially from casein.

Tollens made some observations on parabanic acid obtained with uric and nitric acids.

Scheibler described new acid compounds of tungsten.

Hlasiwetz gave an account of some new derivatives of sulpho-carbonic acid, prepared conjointly with Kæchler. When bisulphide of carbon and ammonia are brought in contact with a third body, which only acts by its presence, like camphor or phenol, colourless, unstable crystals are produced, $C_2H_{10}N_4S_3$. Under the influence of feeble oxidising agents these crystals give rise to the following reaction:—

Rhodanammonium.

$C_2H_4N_2S_4$ forms fine crystals, insoluble in cold water, and resolved by hot water into sulphide of carbon, free sulphur, and sulphocyanide of ammonium. On mixing aniline, sulphide of carbon and ammonia crystals are obtained of the composition $C_{14}H_{18}N_4S_3$, which, if heated with water, yield ammonia, and a body answering to the formula $C_{13}H_{12}N_2S_5$, and crystallising in scales like benzoic acid. It is the sulpho-carbanilide of Hofmann.

Weber treated of anhydrous nitric acid and of a new hydrate of nitric acid.

Lethar Meyer described his arrangement for regulating the pressure of the air in distillation.

Schmitt gave an account of the reaction of chloride of lime on an aqueous solution of the chloride of amido-phenol. In the same manner aniline is transformed into dichlorobenzol.

Grüneberg described experiments made conjointly with Hasenclever on the preparation of chlorine by Deacon's process. Hasenclever and Kemp took part in the discussion which followed.

Tollens described his researches on acrylic acid, undertaken jointly with Caspary. They obtained acrylic acid by means of bromopropionic acid, the preparation by means of allylic alcohol not giving good results. The acid boils at 140° .

Zincke inquired if Tollens had tried oxide of silver or platinum-sponge for oxidising allylic alcohol. Tollens replied in the negative.

Fittig described a new hydrocarbon extracted from coal-tar, having a boiling-point much higher than that of anthracen. It corresponds to the bibasic acid—

Fittig concludes that this new hydrocarbon is phenyl-naphthalin—

The same author gave a communication on allyl-benzol, which he prepared by the action of nascent hydrogen upon cinnamic alcohol. Tollens stated that he had made analogous experiments along with Wagner.

Weddige described the preparation and properties of carbocyanic ether. It is obtained by distilling two parts of oxamithane and three parts of anhydrous phosphoric acid. It is a clear liquid, insoluble in water, on prolonged contact with which it is, however, decomposed into hydrocyanic and carbonic acids and alcohol. If the ether is treated with ammoniacal alcohol, prismatic crystals are obtained, which the author regards as carbocyanic amide, and by means of which and of chloride of carbonyl he hopes to prepare—

Clemens Winkler made a communication on the analysis of gases, Scheibler adding some remarks.

Kolbe described the experiments of Pfankuch on cyanoforn, and those of Saytzeff on hydride of palladium.

Michaelis described experiments on supersaturation. Weber made some observations on the same subject.

Salomon gave an account of his researches on sulpho-carbonic ether. This ether has, in his opinion, the constitution indicated by the formula—

and is obtained by the following reaction—

This body boils at 155° , whilst its isomer—

boils at 161° .

Landolt, on behalf of Schwartz, communicated a memoir on the equivalents of refraction of carbon, of hydrogen and oxygen.

Salkowski, on behalf of Gintl, communicated researches on the action of ammonia on anisic acid and its nitro-derivatives. The author has obtained a number of very interesting amido-compounds.

Hübner, on behalf of Zincke, made several communications. He entered into details on the bromo- and nitro-derivatives of toluen, obtained conjointly with Majort. Then he described experiments made along with Scheibler, from which it appears that anhydrous maleic acid in

presence of hydrogen forms succinic acid. He added that, according to Spezzia, the nitrate of thallium can be used for the analytical separation of chlorine and iodine.

Zincke, on behalf of Schwartz and Gintl, described the action of zinc upon a mixture of chloride of benzol and of an aromatic hydrocarbon. According to the author, the zinc acts here not chemically but by means of its presence.

Liebermann described certain beautiful blue crystals, to which he has given the name *cœrulignon*, and which are found in the preparation of wood-vinegar.

Carstanjen gave a summary of the researches of Schulze on the diffusion of saline solutions. He touched also upon the constitution of allylic alcohol, for which he gave the following "circular" formula:—

which indicates perfectly its relations with glycerin and dichlorhydrin.

Christomenos offered some remarks on a new preparation of diphenyl and diacetyl by electrolytic action.

June 21 and 28, 1873.

These numbers contain no original chemical matter.

Bulletin de la Société Chimique de Paris, tome xix., No. 12, June 20, 1873.

At the meeting of the Society, held May 16, M. Willm exhibited the new bulb apparatus constructed by M. Alvergniat. Three small bulbs, interposed between two large ones, are connected together by S-tubes, so that any gas which it is wished to absorb is compelled to traverse a larger portion of the absorbing liquid than in any other arrangement.

M. Tommasi described certain acid derivatives of naphthylamin, naphthyl-acetamide, and naphthylchlor-acetamide, obtained by the action of chloride of acetyl and chlorated chloride of acetyl upon naphthylamin.

M. Jungfleisch communicated the continuation of his researches on the action of heat upon rotatory powers.

Right camphoric acid, heated in closed vessels with water to the temperature of 150° to 350°, is transformed into two other acids, optically inactive, bearing to it the same relation which inactive tartaric acid and para-tartaric acid do to right or left tartaric acid. These two modifications are reciprocally convertible when heated along with water.

Heat Liberated by the Mutual Reaction of Alkalies and Water.—M. Berthelot.—The author has studied the action of water upon the hydrates of potassa and soda, upon ammonia, upon lime, baryta, and strontia, both hydrated and anhydrous, in order to obtain a thermic measurement of these reactions.

Function of Atmospheric Nitrogen in Vegetation.—P. P. Dehérain.—This important paper will appear *in extenso*.

Observations on a Work by M. Gaudin, entitled, "Architecture of the World of Atoms" (Architecture du Monde des Atomes).—M. West.—The researches of M. Gaudin promise to throw valuable light upon crystallography.

Researches on the Mineral Oils of Buxière-la-Grue and of Cordes.—Jules Jaffre.—An investigation undertaken to ascertain the difference between the mineral oils obtained from bituminous schists and the petroleum of America. The author explains the absence of benzol and of naphthalin in these oils by the fact that the distiller purposely works at temperatures too low to permit of their formation.

A New Method of Assaying Plumbiferous Minerals.—Ant. Mascazzini.—(See vol. xxvii., p. 70.)

Determination of Iodine in Presence of Chlorine and Bromine.—H. Hübner.—The method is based upon

the nearly perfect insolubility of thallous iodide in water, and in solutions of nitre, whilst the corresponding chloride and bromide are moderately soluble. The iodine, bromine, and chlorine should be present in the state of alkaline salts, and the solution should be dilute and neutral. A solution of thallous nitrate is added drop by drop until the precipitate formed is perfectly white. The liquid is then mixed with a little water to re-dissolve the white precipitate, and the whole is allowed to stand for 8 to 12 hours. The yellow precipitate of thallous iodide is then collected upon a counterpoised filter, washed with the smallest possible quantity of water, dried, and weighed. The washing-water contains the whole of the chlorine, which is determined as chloride of silver. The determination of iodine in presence of bromine is effected in the same manner. In both cases it is needful to avoid the use of too great an excess of thallous nitrate, and the addition of too large a quantity of water. The different solubility of the iodide and bromide of lead may also be used to determine iodine in presence of bromine by means of nitrate of lead. This method is less trustworthy than the first mentioned, and cannot be employed for the separation of chlorine and iodine.

Falsifications of Albumen.—A. Herburger.—Albumen is often adulterated with gum, dextrin, and starch. To detect these admixtures, 30 grms. of the sample are dissolved in lukewarm water. After some time the mass is stirred. If the liquid contains many white clots, the quality is inferior; that is, a notable quantity of the albumen has been coagulated by the employment of too high a temperature during desiccation. The solution is mixed with acetic acid, and then some alcohol is added to the decanted acid liquid. If gum is present, a precipitate is formed. If starch has been added, it may be recognised in the usual manner by means of iodine. If the albumen contains sugar, it is easily recognised by the use of Fehling's test.

Quantitative Examination of Iron Mordants.—H. Vohl.—If the mordant in question contains chlorine, it is precipitated by means of sulphate of silver, and the chloride of silver obtained is weighed. To determine nitrous and nitric acids, the filtrate is precipitated with baryta. The sulphuric acid and the oxides of iron are precipitated, whilst the filtrate, after prolonged digestion in heat, contains the nitric and nitrous acids in the state of barytic salts. The precipitate is well washed in boiling water, and the excess of baryta is removed by means of a current of carbonic acid gas. The whole filtrate, with the washings, is brought to a definite volume, say 100 c.c. The presence or absence of nitrous acid is ascertained by means of well-known tests. Then the amount of baryta contained in 5 or 10 c.c. of the liquid is determined, either volumetrically or gravimetrically. If no nitrous acid is present, the whole of the baryta present in solution corresponds to the nitric acid, which is thus determined indirectly. If both nitrite and nitrate are present, a known volume is evaporated to dryness, and the residue is taken up in absolute alcohol, which dissolves the nitrite only, leaving the nitrate untouched. The determination of the baryta in each of these salts gives the respective amounts of nitrous and nitric acids. To determine the ferrous oxide in the mordant, it is diluted with water, and digested in the cold with carbonate of lime in a flask filled with carbonic acid. When the liquid has grown clear, it is filtered in a current of carbonic acid and washed in distilled water. The solution containing the ferrous salt is then oxidised with chlorate of potassa and hydrochloric acid, and the ferric oxide thus obtained is precipitated with ammonia. The presence in a mordant of a ferrous salt and of nitrous and nitric acids is in general injurious. (Few, if any, practical men in England will agree with the assertion conveyed in the last sentence. The quality of an iron mordant may be ascertained much more perfectly by dyeing a swatch of calico with it, and with an extract of logwood, than by the operation recommended above.)

Dyeing Aniline Blacks on Cotton Yarn.—MM. de Vinant.—This process requires great care to prevent the blacks from being clouded:—(1). The cotton-yarn, well boiled out, receives seven turns in a bath composed of 200 grms. of sulphate of copper for every kilo. of material, dissolved in water slightly acidulated with hydrochloric acid. It is then well wrung out. (2). It receives five turns in a bath at 50°, containing 50 grms. hydro-sulphate of soda per litre, and is rinsed. (3). It receives seven turns in a bath of 10 litres of water, 180 grms. chlorate of potash, and 170 grms. sal-ammoniac, dissolved in heat, and then mixed with 480 grms. chloride of aniline. (4). It is stretched out very regularly in a hot drying room at 24° for forty-eight hours. (5). Lastly, it receives four turns at 30°, in a bath containing 1 gm. bichromate of potash per litre, and is well rinsed and dried. If the blacks are reddish, they may be passed through a bath containing 1 litre bleaching liquor at 6° to 100 litres of cold water.

Pearl Grey with Aniline Violets.—Aniline violets applied in very feeble tints furnish pearl greys, whose tone varies with that of the violet employed, and is pure in proportion to the excellence of the dye. As the quantity of colour employed is very small, only the highest class of aniline-violets should be employed. Cotton may be dyed without mordant. The bath should contain a little soap, without acid, though a very small quantity of tartaric or acetic acid is added at the end. For pure wool the colour is dissolved in luke-warm water alone, without acid.

Printing Ink for Use in Calico Printing.—The following mixture gives fine results:—

	Parts.
Venice turpentine	9
Soft potash soap	10
Oleine	4
Lamp-black	6
Bleu de Paris	1
Oxalic acid	0.5
Water	1

The turpentine is first heated along with oleine; then the soap is placed on a levigating slab, and the mixture of turpentine and oleine is very gradually incorporated with it. When this process is complete the lamp-black is worked in, having been first ground and sifted. Finally, with constant grinding, the Paris blue is added, and the oxalic acid and water, which are previously mixed and slightly warmed. The Paris blue and oxalic acid may be replaced with carmine of indigo.

Revue Hebdomadaire de Chimie Scientifique et Industrielle, par Ch. Mène, No. 23, April 11, 1873.

Soaps and Perfumery with an Aluminous Base.—M. Bonnamy.—M. Bonnamy, struck with the inconveniences resulting from the use of toilet-soaps with a base of potash or soda, has prepared alumina soaps. These are, as a matter of course, neutral and free from causticity, and being insoluble in water their detergent action is simply mechanical, not chemical.

Indelible Ink-Powders.—E. Rey.—This paper praises the inks in question, but throws no light upon their composition.

No. 24, April 18.

This number does not contain a single chemical article.

Moniteur Scientifique, du Dr. Quesneville, June, 1873.

The Function of Septic Agents in the Animal Economy, and the Nature of Septicæmia.—Ferrand Papillon, abstracted from the recently-published results of Davaine.—A very important physiological paper. We note the striking fact that, according to the experiments performed, the septic power of putrescent blood stands in no relation with its offensive odour, the latter continuing to increase while the poisonous properties are diminishing.

The Poles in Magnetisation.—E. Duchemin.—A purely physical paper.

A Patronised Ink.—E. Duchemin.—A controversial paper on a so-called "indestructible ink," which Bous-singault had pronounced indelible, and which the author has succeeded in effacing by means of alcohol and benzol.

Experiments on the Effects of Dynamite.—MM. Roux and Sarrau.—Dynamite ignited by violent percussion—*e.g.*, by the detonation of a strong fulminating capsule—explodes even in the open air, and produces an effect, if confined, equal to that of ten times its weight of gunpowder. If ignited in any other manner, it burns quietly if in the open air, and if confined it explodes. But this explosion, whatever may be the temperature and the pressure, is of a different nature. Instead of a detonation, or explosion of the first order, it is merely an explosion of the second order, equal in effect to that produced by double the weight of gunpowder. The experiments on which this conclusion is founded were made with "No. 2 dynamite" of Vouges, containing 50 per cent of nitro-glycerine, and exploded with a Gevelot detonator, containing 0.25 gm. of fulminate. But even with dynamite at 90 per cent the results were found to be quite similar.

Production of Potash Salts at Stassfurt.—Theodore Becker.—A few details on these mines, which have produced so great a revolution in the manufacture of potash salts, will be useful. Stassfurt is situate about 20 kilos. from Magdeburg, on the Anhalt frontier. The geological formation on which it lies is the variegated sandstone. The presence of a bed of rock-salt below this stratum was suspected in 1838. Borings were executed by order of the Prussian Government, and in 1851 the presence of a deposit of rock-salt, at least 330 metres in thickness, was ascertained. The formal working of the mines began in 1857. Before reaching the salt it was necessary to sink 260 metres through the sandstone, the gypsum, and the marl. The saline deposit does not consist exclusively of common salt, and may be divided into four chief regions. The lowest bed is the largest, and consists entirely of rock-salt traversed by slender veins of karstenite. It is about 240 metres in thickness. We find next the region of *polyhalite*, still composed of rock-salt, but intersected by veins of 2 to 3 c.m. thick, formed of *polyhalite*, a mineral composed of sulphates of lime, magnesia, and potassa, agreeing with the formula—

This layer is about 64 metres in thickness, and is composed on an average of 91.2 per cent chloride of sodium, 0.66 of karstenite, 6.63 of *polyhalite*, and 1.51 of hydrated chloride of magnesium. To this stratum succeeds another, of a different composition, and characterised by the presence of a saline mineral named *kieserite*. It consists of mono-hydrated sulphate of magnesia, in small microscopic needles. The layer contains 65 per cent chloride of sodium, 17 of *kieserite*, 13 of *carnallite* (see below), 3 chloride of magnesium, and 2 of karstenite. Its thickness is 56 metres. The upper region is formed of a group of salts chiefly magnesian and potassic, and formerly called *viddancé salts*, because they were at first without industrial application, and were merely extracted to reach the rock-salt below. These salts are now the foundation of the trade of Stassfurt. The principal salt is *carnallite*, a chloride of potassium and magnesium,—

It has a red colour, due to the presence of oxide of iron in microscopic lamellæ. There are found also, in this deposit, *Sylvine* or *Howellite*, a chloride of potassium containing often small quantities of sulphate of potassa, and of sulphate and chloride of magnesium; *Tachyhydrite*, a *carnallite* in which the chloride of potassium is replaced by chloride of calcium; and *Boracite*, a combination of the borate and chloride of magnesium,—

Stassfurt, as we have stated, lies on the Prussian frontier, towards the borders of the duchy of Anhalt. The Prussian workings, therefore, could not be extended to the south-west, where the geological conditions were most favourable. In 1855 the Government of Anhalt commenced operations within its own territory, with perfect success. The saline beds were reached at the depth of 145 metres, and soon a new salt was discovered in great quantity, giving a new impulse to the trade of the district. This is *Kainite*, a compound of sulphate of magnesia and chloride of magnesium. Its discovery enabled the inhabitants to enter upon the manufacture of pure sulphate of potash, which is largely exported to England and the United States. In M. Becker's memoir the reader will find an account of the purification of the crude salts as obtained from the mines. Their applications are numerous. The chloride of potassium is used in the manufacture of saltpetre and carbonate of potassa; the sulphate of potassa is in great demand in the glass and alum-works. Stassfurt exports, also, sulphate of magnesia, chloride of magnesium,—which is extensively used in England for the discreditable purpose of adding to the weight of textile goods, and rendering them hygroscopic,—bromine to an extent almost sufficient for the consumption of Europe, and boracic acid. Lastly, the impure salts obtained as waste in the various refining processes—consisting principally of salts of soda, magnesia, and potassa—are skilfully combined, and sold as mineral manures, more or less rich in potassa and magnesia. The demand for these manures has greatly increased of late years, especially in England and Germany. In 1869 the Prussian mine alone yielded 109,075,000 kilos. of salts of potassa, and 56,332,000 kilos. of rock-salt, representing a total value of 916,960 francs. (It is interesting to note that whereas the application of potassic salts in agriculture, some fifteen or twenty years ago, was found to produce little or no benefit, they are shown by more recent experiments to be highly valuable. This change is what they would lead us to expect. Liebig has shown that the use of manures which contain only *some* of the ash-constituents of the crops only enables the soil to be more rapidly exhausted of the other necessary constituents. We have been for years employing manures containing phosphoric acid, lime, and nitrogen, and our soils are beginning to crave a supply of potash). M. T. Becker's important memoir, on the separation and refining of the various salts and other products above mentioned, will be given at length on a future occasion.

Les Mondes, Revue Hebdomadaire des Sciences, par L'Abbé Moigno, Tome xxxi., No. 9, June 26, 1873.

Determination of the Alcoholic Strength of Liquors.—If an alcoholic or acetic solution is allowed to flow from a small orifice, the drops are the larger and heavier the more concentrated is the solution. Hence, if we count the number of drops necessary to make up a certain volume, we may, by means of a special table, determine the strength of wine, beer, or vinegar.

New Material for Paper-making.—Messrs. Jourdeuil, Parisot, and Co., of Beire-le-Chatel (Cote d'Or), have patented the stem of the hop as a material for the manufacture of paper.

No. 10, July 3, 1873.

Portable Liquid Gas.—M. Roche, of Paris, has contrived a lamp for burning the light mineral oils without danger or nuisance. He asserts that his lamp consumes, per hour, 50 grms. of light oil, giving a light equal to that obtained from the combustion of 200 cubic metres of coal-gas, the cost ranging according to the price of the oil in different localities, from 1 to 5 centimes.

Zinc-Green.—Elsmar manufactures zinc-greens by mixing 5 parts oxide of zinc, 1 part sulphate of cobalt,

and water enough to form a paste. This mass is thoroughly incorporated and heated to redness, when it yields a fine powder, of a deep green. If the amount of oxide of zinc is increased to 10 parts a grass-green is obtained, and with 20 parts a still lighter. The last proportion serves as a substitute for the dangerous poison known as Schweinfurt-green.

Reimann's Färber Zeitung, No. 25, 1873.

This number contains receipts for dyeing apple-green on wool, cochineal-red on cotton yarn, for which the reader is referred to an advertisement, and Vert Horizon on silk.

Solution of India-rubber for the Manufacture of Elastic Tissues.—The raw india-rubber is soaked in clear water, and boiled for about an hour to remove dirt. It is then taken out of the water, and cut into round slices about 1 centim. in thickness. It is then rolled out into layers about 2 metres long and 0.15 metre broad. The rubber is then dried in a warm chamber. After the drying follows the solution. About 26 kilos. of rolled caoutchouc are placed in a wooden vat lined with zinc, and treated with a mixture of 50 kilos. benzol and 70 kilos. oil of turpentine. Both these liquids must be perfectly free from fatty matters, or the solution of india-rubber will be useless. The caoutchouc, before being brought in contact with the solvents, is torn up into small fragments. The mass is stirred occasionally till it forms a thick, homogeneous liquid. To test the benzol and turpentine, small portions of each are evaporated to dryness in the water-bath. If any trace of fat remains the sample is at once rejected.

The Editor gives also receipts for a Russian green on wool, for yellowish brown, red-brown, and alkali-blue on cotton; and for printing rainbow styles in rose, blue, and orange.

Products of Resin.—Schröder, during an investigation of the oxidation-products of rosin (colophonium), discovered an amorphous resinous acid, isophthalic and trimellitic acid—a derivative of the acid occurring in mellite.

New Washing Agent.—A contemporary journal, devoted to the art of dyeing, informs us that *paraffin* is now used instead of benzol or turpentine for cleansing textile fabrics!

Utilisation of Old Dye-Liquors.—As a means of extracting from such liquors everything of value, it is proposed that the bath in which scarlet has been dyed should be gradually exhausted by dyeing with it successively lighter and lighter shades. A better proposal is, where practicable, to keep one and the same bath for the same colour. (Many experienced scarlet-dyers maintain that an old lot gives the best results.)

Dressing for Silks.—A solution of gum tragacanth is recommended. Silks got up in this manner do not show rain-spots.

NOTES AND QUERIES.

Lemon-Yellow.—I shall take it as a great favour if you or any of your correspondents will kindly inform me how to make a bright lemon-yellow from chromate of potash and nitrate of lead—a yellow that will keep its colour on exposure to the air and after being well washed; I have tried many experiments, but they all change to a deeper colour. If you can give me any hints about the same, I shall feel greatly obliged.—L. C.

TO CORRESPONDENTS.

Miss B.—Your enquiries should be addressed to a medical paper.
Volta.—Prussian blue, dark ultramarine, or finely-ground indigo may be used; but there are no pigments soluble in linseed oil.
J. F. Armstrong, H. W., and others.—Messrs. Traubner and Co., Ludgate Hill, would procure it for you.

THE CHEMICAL NEWS.

Vol. XXVIII. No. 712.

PHRASEOLOGY EMPLOYED IN TEACHING FUNDAMENTAL FACTS IN CHEMISTRY.

By C. R. A. WRIGHT, D.Sc. (Lond.),

Lecturer on Chemistry in St. Mary's Hospital Medical School.

(1). The phraseology ordinarily in use in the description of fundamental chemical phenomena is open to the objection that either it is diffuse and wanting in terseness and precision, or else words are employed which go beyond the requirements of the moment, inasmuch as they connote not merely the facts themselves but also hypotheses, the full discussion of which is impossible at the commencement of a course of instruction; in consequence, a tendency to one-sidedness in looking at questions concerning theory and speculation is often unintentionally developed. The student, being taught to take certain matters of this kind for granted during the early part of his course of study, is frequently unable to divest himself wholly of preconceived notions on the subject at a later period in his course of study, when he comes to examine the bearings and scope of these hypotheses. To render the fallacy of *petitio principii* less imminent, the mode of teaching certain fundamental doctrines briefly described below is suggested, the method having been tested by some years' trial and found to meet the requirements of the case, viz., enabling the facts themselves to be stated in terse language, without involving in any way any assumptions or hypotheses whatever beyond certain universally admitted conventions.

(2). Quantitative analysis shows (Dalton) that any pair of so-called elements capable of being obtained from a given homogeneous compound* (and hence stated in ordinary language to exist in, or be components of, that compound) are present in that compound in proportions by weight, related by a simple numerical law to those in which the same pair of elements exist in any other homogeneous compound; this law of multiple proportions being that if the relative quantities by weight in which any two elements co-exist in a given compound be represented by a and b , the relative quantities in which they co-exist in any other compound are indicated by a and $\frac{m}{n}b$, where m and n are integers rarely of high values.

Like all experimental generalisations, this statement only expresses the result of any given experiment within a certain degree of approximation; but it is uniformly found that the more care be taken in the quantitative determinations of the substances present, the more accurate the processes employed, and the greater the purity of the body operated on, the more nearly is the result of each experiment expressed by the generalisation.

(3). It hence follows that the composition by weight of all homogeneous compounds is indicated by the general formula, $x_1c_1 + x_2c_2 + x_3c_3 + \dots + x_nc_n$, where—

$$c_1, c_2, c_3, \dots, c_n$$

are certain numbers applied respectively to each of the n known elements, and $x_1, x_2, \dots, x_n$ coefficients, the values of which are 0 in the cases of such elements as are not present in any given compound under consideration, and are simple integers in the cases of such elements as are present in that compound. The value of the c 's thus

* Solutions and other apparent exceptions to this rule are generally viewed as not being homogeneous compounds, but as being simply indeterminate mixtures of two or more dissimilar substances.

obtained from quantitative analysis, and so chosen that the values of the x 's in the general formula shall be as low as possible in most cases, constitute what are spoken of as the combining numbers of the elements. Thus, 1, 6, and 8 being the combining numbers of hydrogen, carbon, and oxygen respectively, many compounds of these elements have compositions expressed by the formula $m \times 1$ (of hydrogen) $+ n \times 6$ (of carbon) $+ p \times 8$ (of oxygen), where m, n , and p have very simple values. Thus—

Water	$m=1$	$n=0$	$p=1$
Carbonic acid ..	$m=0$	$n=1$	$p=2$
Carbonic oxide ..	$m=0$	$n=1$	$p=1$
Marsh-gas	$m=2$	$n=1$	$p=0$
Acetic acid	$m=1$	$n=1$	$p=1$
&c., &c.			

From these considerations, then, are derived what are spoken of as the "Old series of combining numbers" (Dalton, Berzelius, &c.).

(4). Manifestly any one of this series of numbers might be multiplied or divided by a simple integer without invalidating the applicability of the general formula. Thus, if $2c_n$ were taken as the combining number instead of c_n , a compound indicated by the formula—

$$x_1c_1 + x_2c_2 + \dots + x_nc_n$$

on the old scale would be indicated by—

$$2x_1c_1 + 2x_2c_2 + \dots + 2x_n(2c_n)$$

or if $\frac{c_n}{2}$ were taken instead of c_n , the same compound

would be indicated by— $x_1c_1 + x_2c_2 + \dots + 2x_n\left(\frac{c_n}{2}\right)$

For convenience, a "new series of combining numbers" is constructed (Gerhardt, Canizzaro, &c.), where the combining numbers are in some cases identical with the old ones, in others are multiples of them, the precise value of each number being fixed by reference, not merely to gravimetric composition, but also to volumetric composition and the specific gravity of the substances concerned in the vaporous state (Criterion I.). When this criterion is inapplicable, a convention based upon specific heat is taken (Criterion II.); and where both of these criteria are inapplicable, chemical analogy is taken as Criterion III.

(5). Criterion I.—Experiment shows (Gay-Lussac) that a given bulk of any compound vapour contains a volume of any volatile component element (examined under the same circumstances of temperature and pressure) which is an integral multiple of a simple fraction of the bulk of the compound vapour; i.e., one volume of compound vapour contains $\frac{m}{n}$ volumes of each vaporous constituent element, m and n being integers rarely of high values, and varying in value with each constituent and with the nature of the compound.

(6). As a subsidiary unit of volume (the absolute unit being 1 cubic metre) is chosen the (variable) bulk occupied by 1 grm. of hydrogen under the conditions that obtain during any given experiment under consideration. This unit, which may be conveniently designated as a *metropneum* (*μετρον* and *πνευμα*) has, at a pressure p and a temperature t , approximately the value—

$$0.0112 \times \frac{273+t}{273} \times \frac{760}{p}$$

absolute units of volume. Hence one metropneum of compound vapour contains $\frac{n}{m}$ metropneums of any given gaseous elementary constituent, m and n being integers.

(7). The vapour density of any given constituent being s in reference to hydrogen, $\frac{n}{m}$ metropneums of that constituent must weigh $\frac{n}{m} \times s$ grms.; i.e., one metropneum of

compound vapour contains $\frac{ns}{m}$ grms. of any given vapor-

ous elementary constituent, Taking into consideration all the volatile compounds of this element (*i.e.*, all the different values which the expression $\frac{ns}{m}$ can have, n and s being constant), there must be a greatest common measure of all these values; the numerical value of which G. C. M. must be $\frac{s}{m}$, when n has in each case the minimum integral value possible.

Thus the following values of the G. C. M.'s are obtained:—

Hydrogen ..	0.5	Mercury ..	100.0
Nitrogen ..	7.0	Arsenic ..	37.5
Oxygen ..	8.0	Phosphorus ..	15.5
Sulphur ..	16.0	Bromine ..	40.0
Chlorine ..	17.75	&c., &c.	

The values of m in the expression $\frac{s}{m}$ (when this expression is the G. C. M.) being found to be—

1. In the case of mercury (probably zinc, cadmium, &c.).
2. In the case of hydrogen, oxygen, chlorine, bromine, iodine, probably potassium (Dewar and Dittmar), nitrogen, sulphur (at high temperatures), &c., &c.
4. In the cases of arsenic and phosphorus.
6. In the case of sulphur (at comparatively low temperatures).

(8). Hydrogen being conveniently made a standard of reference, its combining number is taken as unity; hence, all the other numbers require to be doubled: whence the following equation— $C_n = 2g_n$, when C_n is the combining number (new series) applied to any given element, and g_n the G. C. M. for that element obtained as above from the vapour density of the element, s , and the experimental determination of the minimum value of m .

(9). Many elements not themselves volatile at measurable temperature yield volatile compounds with other elements; *e.g.*, carbon, boron, silicon, iron, &c. When several volatile compounds of a given element are compared, it is uniformly found that the numerical values of the weights of that element contained in a metropneum of each compound vapour respectively have a G. C. M., just as the numerical values of the weights of any volatile elements contained in a metropneum of all its compounds respectively have a G. C. M., viz., $\frac{s}{m}$.

Twice the value of this G. C. M. is similarly taken as the combining numbers of the element in question (new series).

(10). The experimental errors involved in vapour density determinations are frequently of such magnitude that the results of any one given experiment only approximate to those which would be in exact conformity with the generalisations of the existence of a G. C. M. of the weights or volumes of a given element contained in a metropneum of the vapours of each of its compounds; still, the more care is taken in avoiding sources of error, the closer is the approximation.

Where a combining number is fixed by the determination of a G. C. M., it is evident that the existence of only one or two volatile compounds renders the determination impossible or unsatisfactory; *i.e.*, the combining number thus deduced is not always identical with that fixed by Criterion II. or III. (*infra*). Thus, from the vapour density of ferric chloride, 112 would be taken as the combining number of iron; but both the specific heat of metallic iron and analogy with aluminium (the combining number of which, deduced from the chloride, is double of that deduced from the methide and ethide, Buckton and Odling), indicate 56 as the combining number.

Compounds that decompose on heating, or "dissociate," are of course excluded in the determination of a G. C. M., there being no longer one homogeneous body to deal with in such cases.

(11). Criterion II.—In the case of all elements that are solid at measurable temperatures, and the melting-points

of which do not greatly exceed the melting-point of platinum (*i.e.*, in the case of all elements that give volatile compounds, save those gaseous at the common temperature, carbon, silicon, and boron), it is found that the apparent specific heat of the solid element between t° and $t^\circ + 1$ (where t° lies between -50 and $+100$) closely approximates to $\frac{6.5}{c}$, where c is the combining number

(new scale); or $c = \frac{6.5}{h}$, where h is the apparent specific heat.

In the case of elements where Criterion I. is not applicable, it is found that a very simple multiple of the combining number (old scale) (§ 3) also closely approximates to $\frac{6.5}{h}$; this multiple of the old combining number is then

taken as the combining number (new scale).

Thus the combining number of iron (old scale), deduced from gravimetric analysis only, is found to be 28; the apparent specific heat, however, closely approximates to $\frac{6.5}{2 \times 28}$; wherefore, 2×28 , or 56, is taken as the combining number (new scale). Similarly, '113.4' is taken as the combining number of indium (Bunsen), instead of $37.8 = \frac{113.4}{3}$, as deduced from gravimetric analysis only.

(12). Criterion III.—The particular cases of the general expression, $x_1c_1 + x_2c_2 + x_3c_3 + \dots + x_nc_n$, produced by varying the values of the x 's, may be briefly denoted by applying to each element actually present in a given compound a symbol indicating its name and combining number, and repeating each symbol as many times as is denoted by the value of the x attached to that symbol in the particular case examined. Thus, a collection of symbols, termed a *formula*, is obtained; when the x 's have the minimum possible values, the formula is termed an *empirical formula*. Thus, water is indicated by the empirical formula HHO; butyric acid by CCHHHHO. This notation is conveniently abbreviated by writing a suffix, x , instead of repeating the symbol x times; thus—Water, H_2O ; butyric acid, $C_4H_8O_4$.

(13). Formulae, however, may be made to indicate not only the ratio by weight and volume in which the components are present, but also their vapour densities. From the circumstance (§ 8) that double the G. C. M. for any given element is taken as the combining number of that element, it follows that the empirical formula of a compound must indicate either the weight of two metropneums of that compound, or a sub-multiple thereof; and hence, by multiplying the empirical formula by some suitable integer, a formula (termed the *rational formula* of the compound) is obtained, which denotes not merely the gravimetric and volumetric composition of the compound, but also the absolute weight in grammes of two metropneums of its vapour. Thus, the rational formula of water is identical with the empirical formula H_2O ; the rational formula of butyric acid is double its empirical formula, being $C_4H_8O_4$.

(14). Elements which do not yield volatile compounds, and the apparent specific heats of which are unknown, have combining numbers which are fixed by this convention; such multiples of the numbers deduced from gravimetric analysis (§ 3) are taken as will enable compounds of these elements to be indicated by formulae which resemble in suffix values the rational formulae of compounds of other elements to which the first-named compounds are chemically analogous.

Thus (apart from evidence derived from Criteria I. and II.), the rational formula of aluminic chloride is Al_2Cl_6 ; ferric chloride is chemically analogous to aluminic chloride, and can be indicated by a similar formula, Fe_2Cl_6 , if the value denoted by Fe (combining number, new scale) be made = 56.

(15). The symbols involved in chemical formulae, though

unlike algebraic ones in this respect, that juxtaposition does not mean multiplication (the sign + being understood between each pair of adjacent symbols), are yet like them in one property, viz., that of commutation; by adopting fixed conventions as to the mode in which the symbols in a rational formula are arranged among themselves, many facts in the chemical history of a compound may be indicated. Thus, the rational formula of acetic acid being $C_2H_4O_2$, or $CCHHHHOO$, a great many facts and chemical changes in which acetic acid is concerned may be at least partially indicated and called to mind by arranging these eight symbols thus— $CHHHCOOH$, or $CH_3.CO.OH$. Formulae whose constituent symbols have been thus arranged, so as to connote points in the chemical history of the compound indicated, are referred to as *dissected formulae* (structural formulae).

(16). From the above definition of a rational formula, it is evident that every such formula indicates the same bulk, viz., two metropneums; the concrete weight in grammes of this bulk of compound is conveniently referred to as a *metrogramme* (or *metrogram*). Thus, the metrogram of water is 18; i.e., 2 metropneums of steam weigh 18 grammes.

(17). In the case of elements, rational formulae are applied, based on the same principles as those in use for compounds. Since $2\frac{s}{m}$ is by definition the combining number (§ 8), and, as $2s$ indicates the weight of 2 metropneums, m must indicate the number of times the symbol is repeated in the rational formula of the element; thus—

Element.	Rational Formula.
Mercury	Hg
Hydrogen	HH or H_2
Chlorine	ClCl or Cl_2
Oxygen	OO or O_2
Ozone	OOO or O_3
Phosphorus	PPPP or P_4
Sulphur (at low temperatures) ..	SSSSSS or S_8
" (at high temperatures) ..	SS or S_2

It may be noticed, *en passant*, that allotropic modifications are often indicated by different rational formulae; e.g., oxygen and ozone, or the two allotropic sulphur vapours.

(18). The rational formulae of non-volatile elements and compounds are necessarily indeterminate; in this case the convention is adopted that the empirical formulae are regarded as the rational ones (unless reasons based on analogy or chemical properties lead to higher formulae). The empirical formula of an element necessarily consists of a single symbol; thus silver is considered to be indicated by the rational formula Ag; analogy with hydrogen and potassium, however, would lead to the rational formula Ag_2 .

Chloride of sodium similarly is assumed to have the rational formula NaCl, although it is not at all improbable that a higher formula may hereafter turn out to be the rational formula.

In most cases analogy and other circumstances are in favour of the identity of the empirical and rational formulae, but not always. Thus (apart from vapour density) the empirical formula of ferric chloride is $FeCl_3$; analogy with aluminic chloride would double this formula, and the determination of the actual vapour density of ferric chloride also gives the rational formula Fe_2Cl_6 .

(19). The term a *proportion* may be conveniently used to indicate not a fixed concrete amount like the metrogram, but a *relative weight*—which is taken in the ratio of the metrogram in the case of compounds, in the ratio of the combining number in the case of elements. Thus—

1 proportion of hydrogen = 1 part by weight.
 " " oxygen = 16 parts "
 " " water = 18 " "

(20). By the use of the terms *combining number* (new scale), *metropneum*, *metrogram*, and *proportion* as above

defined, the fundamental facts connected with the gravimetric and volumetric composition of substances, and their vapour densities, can be expressed in terse language which involves no hypothetical assumption whatever. Thus the essential facts connected with water are—

1. Oxygen, hydrogen, and no other elements are present in water.
2. These elements are present in the respective weights 8 and 1.
3. These elements are present in the respective volumes 1 and 2.
4. The vapour densities of steam and oxygen are respectively 9 and 16 in reference to hydrogen.

Then the phrase "one proportion of water contains one proportion of oxygen and two of hydrogen," or "one metrogram of water contains half a metrogram of oxygen and one metrogram of hydrogen," indicates all these facts, it being remembered that the rational formulae of oxygen and hydrogen are O_2 and H_2 respectively.

All the advantages of succinctness and terseness possessed by such phrases as the following—"the molecule of water contains two atoms of hydrogen and one of oxygen, the molecule of oxygen containing two atoms of oxygen, and that of hydrogen two atoms of hydrogen"—are thus gained without the use of language necessarily involving hypotheses or assumptions; and hence, by employing the terms above defined, the mind of the student may be left wholly free to appreciate the just value of such hypotheses when his knowledge of facts is sufficiently extensive to enable him to understand their bearings.

ON A COMBINATION OF UREA WITH CHLORACETYL.*

By M. D. TOMMASI.

THIS compound, which results from the substitution of an atom of monochloracetyl, C_2H_3ClO , for an atom of hydrogen in urea, and which I shall designate by the term chloracetyl-urea—

is produced by the direct combination of urea with chlorated chloracetyl.

In order to prepare this compound, there is introduced into a long-necked flask, well dried, a molecule of urea previously desiccated at 100° , and a molecule of pure chloride of chloracetyl. The mixture of the two bodies is effected without disengagement of heat; but soon there is established a brisk reaction, the mass becomes liquid, strongly heated, and commences ebullition; quantities of hydrochloric acid are disengaged, and at the same time a white solid mass attaches itself to the sides of the flask. This reaction should be left to itself, and when it is terminated the flask should be heated for some hours on a water-bath until the reaction is completed, which is expressed by the following formulae:—

The white product which covers the sides of the flask is washed several times with cold distilled water, pressed between folds of paper, and dissolved in boiling alcohol; the alcoholic solution is to be filtered, and allowed to remain during twenty-four hours. At the end of this time the capsule will be covered with beautiful light yellow-coloured crystals, which may be purified by several crystallisations in alcohol with some animal black.

Chloracetyl-urea crystallises in fine colourless needles

* Communicated by the Author.

insoluble in cold water, slightly soluble in boiling water. Alcohol at 40° density dissolves it feebly in the cold, and in rather greater quantity with heat. Heated on an oil-bath in a test-tube, it commences to decompose at a temperature of 160°; at the same time a small portion of the unaltered product is sublimed and deposited on the cold sides of the tube in fine white and silken needles. Heated on a plate of platinum, chloracetyl-urea melts and disengages white vapours. Fuming nitric acid attacks it at the ordinary temperature, with disengagement of gaseous products, amongst which I have ascertained the presence of carbonic acid. Concentrated nitric acid very slightly dissolves it in the cold, in greater quantity with heat without decomposition. The behaviour is the same with sulphuric, hydrochloric, and acetic acids. Chloracetyl-urea is not precipitated by mercurous nitrate, nor by nitrate of silver. When we cause nascent hydrogen to react on chloracetyl-urea, in the place of obtaining acetyl-urea and hydrochloric acid, as the following equation would indicate:—

we obtain a crystallisable compound very soluble in cold water. Not having at my disposal sufficient quantity of this new product, it has been impossible for me to analyse it.

The analysis of chloracetyl-urea has given the following results:—

	Calculated, (C ₂ H ₂ ClO ₂ N ₂)	Observed.	
Carbon ..	26.37	27.01	26.52
Hydrogen ..	3.66	3.87	3.69
Chlorine ..	26.00	25.99	25.46
Nitrogen ..	20.51	20.11	20.63
Oxygen ..	23.46	"	"

When a small quantity of chloracetyl-urea (about half a milligramme) is placed on the end of the tongue, we experience no particular sensation: but soon, at the end of two or three minutes, there occurs a burning taste in the larynx, accompanied with sharp pain and a sensible difficulty of respiration. These symptoms disappear ordinarily in an hour.

We may conclude, from experiments made on animals, that chloracetyl-urea does not belong to the class of violent poisons.

These researches have been made at Sorbonne, in the chemical laboratory of M. Schützenberger.

INDIUM IN AMERICAN BLENDES.

By H. B. CORNWALL, E.M.

In a specimen of zinc blende from W. Ossipee, New Hampshire, handed me by Mr. Lewis, of the firm of Webster and Lewis, metallurgists, I have detected by the spectroscopy a notable amount of indium. The blende is resinous in appearance, with rather large cleavage surfaces, and is extensively mined for the purpose of obtaining lead and silver, as it carries a considerable proportion of somewhat argentiferous galena. It was examined by the method given by Richter in Plattner's "Manual of Blow-pipe Analysis," viz., solution in nitro-hydrochloric acid, filtration, and precipitation of the oxides of iron and indium with a sufficient excess of ammonia to re-dissolve the oxide of zinc. The precipitate, collected on a filter and thoroughly dried, was then moistened with hydrochloric acid, and tested with the spectroscopy, giving one distinct indium line.

A second specimen, from the cabinet of the School of Mines, labelled Eaton, N.H., also gave a fainter indium reaction, but, as it is very similar in appearance to the above blende, I think they are probably from the same vicinity. To obtain the indium spectrum from this second

specimen, it was necessary to repeat the operation of moistening the oxides and bringing them into the flame two or three times, as thus the chloride of copper spectrum, due to imperfect washing of the precipitate, grew gradually less intense, and the indium line could be discerned flashing out just as the oxides were brought into the flame, and before the chloride of copper spectrum appeared.

On this second specimen I also tried precipitating the indium from the original solution with zinc, after evaporation with sulphuric acid and separation of the sulphate of lead, but the indium line could not be seen much better than by the other method, which is more rapid.

The following blendes were examined without showing indium:—From Warren, N.H.; Wurtsboro', Ellenville, and Lockport, N.Y.; Phoenixville, Friedensburg, and Wheatley Mine, Pa.; Ducktown, Tenn. (the variety rathite); Shulsburg, Wis.; and Galena, Ill.

PS. Since writing the above, I have examined blendes from Silver Hill, N.C.; Prince's Bay, Lake Superior (with native silver and calcite); Alpine Co., Col.; and Roxbury, Conn. The Roxbury blende contains so much indium that it can be detected in the raw powdered blende, without using acids.—*American Chemist*.

ON THE ENERGIES OF THE IMPONDERABLES, WITH ESPECIAL REFERENCE TO THE MEASUREMENT AND UTILISATION OF THEM.*

By the Rev. ARTHUR RIGG, M.A.

(Continued from p. 17).

We are indebted to "energy" for all we have, and all that men have won. For example, this building and all that it contains is an example of one of the energies of gravity. The lightning, with its thunder, is an example of the energy of electricity. Power of hearing and of speaking are examples of the energy of vitality. The bread eaten and the wine drank are assimilated and become ours by the energy of affinity. It is owing to the energy of light that vision can be had; and to the energy of heat that railways and locomotion can be utilised.

The word "energy" itself, which has in these days, Phoenix-like, risen from its ashes, and which plays so important a part in the title to this course of Cantor lectures, may properly claim some notice.

The word has been adopted, rejected, and revived. It seems to have been first used by Lucretius, a Roman philosopher, who was born B.C. 95 and died B.C. 55. The word had been forgotten or laid in oblivion until Dr. Young, in his lectures at the Royal Institution in 1807,† explained what he meant by energy, and illustrated his meaning by the impact of an ivory ball or balls upon a line of suspended balls.

Here are several ivory balls suspended so as to touch each other. If the end one be raised a little, and then allowed to fall, the ball at the other end will be driven away. The motion in the last ball resulted from energy expended in the raising of the first ball, and this first ball was raised by the energy of vitality. When, however, vitality no longer puts forth energy, then the energy of gravity operates, and causes the ball to fall. Such a simple experiment revived the word "energy," which has thus been re-introduced, and bids fair to hold an important place in science annals for some years.

* The Cantor Lectures, delivered before the Society of Arts.

† In Lecture 8, Young wrote:—"The term 'energy' may be applied with great propriety to the product of the mass (or weight) of a body into the square of the number expressing its velocity." This is not "energy" according to modern usage, but, for reasons which need not at present concern us, it is double of that to which in these days the term "energy" is applied.

Energy is from two Greek words, *en*, within, and *ergon*, work; used in its true sense, it means the work "that is within." Whenever, then, we find that a power to do work exists, we may say, "there is energy." It needs not that the work be done, it is immaterial how long it has lain dormant, or whether it be in man's estimation great or small; we only need the assurance that there is the capacity to do. A loaded gun need not be discharged to assure us that in that which is in the gun is energy, and yet to ascertain or measure the energy the discharge must take place. When that has happened, we may say, within the gun is no energy. The gun itself is merely a contrivance by which certain combinations may be induced to exercise their energies; it has nothing to do with the communication or even introduction of the energy utilised. When the energy is within the barrel, and inoperative, we handle and play with the gun, disregarding the thought of energy, but when the energy of quiescence is to become energy in action, it behoves us to play with the gun no longer.

But how can the gun be again a means or an agent through which some one or other energy may re-manifest itself. Clearly by another group of quiescent energies being introduced. This illustration of an expended and a re-introduced energy may suffice to give a character to an element in respect of all the energies, viz. their expenditure and re-introduction or re-creation. Either through the innate operation of natural causes or through the agency of vital energy, there must be a restoration. These restorations are effected in ways to which the name of legion may be applied. For example, a weight requires energy to raise it, a spring requires energy to bend it, air in a gun requires energy to compress it, before any of these can be said to have energy in possession. The water in a mill-pond has been raised by the energy of the sun. The chemical affinities in a galvanic cell are innate. A labourer and a horse require food that they may work. So with many similar illustrations. In all these is a dormant or quiescent energy. Once let it loose and the Arabian Night's story of Sinbad and the Giant, or that boast of *Owen Glendower*, that he could

"Call spirits from the vasty deep,"

would not be met with *Hotspur's* taunt—

"Why, so can I, or so can any man;
But will they come when you do call for them?"

These energies always come when rightly summoned.

Observe, energy presents itself in two forms—energy in quiescence, and energy in action. To these forms technical names have been given. Energy in quiescence is called potential energy; and energy in action is called kinetic energy. In this weight, suspended as pendulum, these two energies may be illustrated. If the weight be struck from its lowest position, then the kinetic energy of vitality as manifested through muscular action, sets it off. But if the weight be elevated and simply let fall, then the potential energy stored up in the act of lifting becomes kinetic energy, through the influence of what we call gravity.

To sum up. Belonging or attached to all that is material are certain powers or influences which cannot be separated and so weighed; hence these powers or influences are said to be "imponderable." Since these powers or influences affect the motions of bodies they are called forces, for force is that unknown influence which causes, retards, stops, or accelerates motion.

Again, when by such arrangements as nature calls into play, or men can contrive, these forces manifest themselves in action, they are said to be energetic.

Now, since we can plan to some extent how and when each force should manifest its energy, and obtain or retain the results, these results are called work. This may be measured or weighed, and it is through such work alone that a value can by men be placed upon the forces of the imponderables, which, by their energy, have done work.

The measurement, therefore, of the energies of the imponderables resolves itself into a measurement of the work they do. It is, therefore, very essential that the measurement of work should be by means easily reproducible, scientifically accurate, of universal application, beyond all question and all cavil, admitting of no elements which, under any circumstance, could vitiate or falsify a conclusion.

Three elements only are needed to fulfil these conditions, viz., the *mass* of the body moved, the *space* through which it moved, and the *time* during which by the operation of some force it was being moved. These three elements being known, all others or varieties can be derived from them; hence all others are called *derived* measurements. Reasoning thus, a pound weight from which mass may be deduced, a two-foot rule by which space may be measured, and a clock by which time may be noted, are all that we require in England in order to determine measurements of work. But very clearly these three sources of fundamental units must be of an irreproachable character. Speaking generally, who dare venture to say that the pound weight he has, or the clock he has, or the two-foot rule he has, is more to be relied upon than the corresponding instrument in the possession of his neighbour? 'Tis amusing to listen to the pleadings of the owners of watches and two-foot rules, and scales and weights, as to the wonderful accuracy of those they possess.

Where lies the appeal? Who shall decide whether the second ticked by the watch which cost thirty shillings or that ticked by the chronometer which cost one hundred pounds is to be the true second? Who shall decide the inch and the pound when the owners disagree? The answer to these questions, doubtless, raises in your minds forms of difficulties not easily solved.

It may suffice, for this evening, to glance at one or two of these difficulties, in order that we may not think it a trifling with important interests in what, perhaps, seems a kind of childish quibbling, to suggest as a difficulty in such common affairs as a pound-weight, a second, and an inch. Let us first see that from these can be had all we use as measures.

When we say of anything it measures ten, twenty, thirty, or forty, we may add the words inches, feet, yards, or miles. These words must be in some way related. The measurement thus expressed consists of two parts, a numerical and a denominational one. The numerical is absolute and independent of the denominational one. This latter is, for a special case, the unit of measurement; hence there may be a great variety of units, all, however, by their inter-relations, capable of being resolved into one. This one, this original, this is the difficult one to decide, and to it a portion of the next lecture must be given.

So far, then, for the unit of space. Now as to time. Let anyone attempt to measure time by the repetition of a unit derived from any ordinary source, and he will soon find himself in a labyrinth of doubts. All our measures of time are derived from astronomy. Of the unit of this our future grain there is the compound measure which some may say is put beyond the reach of such disparaging remarks, viz., that invaluable measure in all commercial transactions, the pound weight. Time is our own; we waste it as we please; we do not pay for it. Space is our own; we can walk where and as we please; but, as to our food, that is ours by purchase, and we buy it by the pound weight.

Well, "truth," the proverb says, "is mighty and must prevail." The pound weight is quite worthless as a scientifically accurate and universal measure. There is really no such thing as weight for a universal measure, and yet nobody ever bought a pound of sugar without thinking they were getting at one time the same quantity as at another. That is not the case. Weight, speaking accurately, is a most variable measure, and is therefore one on which no reliance is to be placed in scientific

investigation. What we do measure, scientifically speaking, when we speak of weight, is mass, and an endeavour shall be made to show you the difference between mass and weight.

First, weight is not at all to be relied upon. Here is a jar of water balanced on a scale-beam, but so as to hardly equal the weights on the other side. If I put my finger in the jar, the jar overbalances the weights. But why should the scale-pan sink when one simply touches the water with the hand? It is not pressed down. The hand is merely put into another atmosphere, water, instead of air. Lest anyone should think that the jar is pressed down, let a weight hanging by a string, which sustains the weight, be suspended in the water, still the scale pan in which the jar of water is descends. Therefore the weight appears to be altered—there seems something or other about it which is not altogether correct. The matter presents itself again in this form. Here is a scale-beam with a block of wood at one end, and an exactly balanced weight at the other. Now, as the weights pass from one atmosphere to another they change in their relationship; and whilst the mass or quantity of matter contained in this block of wood and in this counterpoising weight remains the same, yet the relation of the weights does not remain the same. Some may say that if the matter undergoes no change, then the weight undergoes no change. It is the weight which undergoes a great change, but the matter undergoes no change. At present, both are in an atmosphere of air, and you see that the beam is in exact equilibrium; but now let each be immersed in an atmosphere of water, and you see at once how the relationship to each other is changed; they no longer balance. The mass of wood is the same as before, and, therefore, as far as moving from one atmosphere to another is concerned, masses must be considered, and not weights; therefore, where the atmosphere changes, there we must give up the idea of weight. There is another cause why weight will not act as a standard unit. Weight results from the action of gravity; it is not a property of matter at all. If we change the force of gravity which tends to pull a mass down, we then change the amount of pressure that the mass exerts on a spring. If we take a mass of matter at one of the poles, it is nearer to the centre of the earth than if it were at the equator, and in consequence it will be pulled down with greater force, so that what would weigh (say) 14 lbs. by a spring balance at the pole, would weigh (say) 14 lbs. at the equator. Therefore, if we ordered a quantity of goods to be sent from some place near the poles towards the equator, and they were weighed by a spring balance, they would not weigh so much on reaching their destination as they did when they were shipped; and yet the quantity of matter would be exactly the same.

Observe, it is a spring balance, and not a scale beam, that is used. A spring balance measures force only, viz., in this case the depressing or pulling down force of gravity at the place where it is used. With a spring balance a gravitation experiment is made. If a scale beam be used, then as the change of gravity affects the weight in each scale pan equally, the relations between them will not be affected, and the scale beam will be in equilibrium when the contents of the scales are influenced by the varying force of gravity.

You saw, a short time ago, that weight varies by taking the mass into an atmosphere denser than that in which we live, and now you shall see the same result by changing the atmosphere for one more rare. Here is a glass beaker, suspended bottom upwards by a hook, so as to exactly balance a weight at the other end of the cord; the system is now in equilibrium. I will change the atmosphere within the beaker by admitting some ordinary coal gas into it, and you see the weight changes at once; the beaker appears to be lighter. These illustrations show that dealing with weight, we deal with that which is variable in all parts of the earth, and, owing to

atmospheric changes, variable at the same time almost in the same position. Doubtless all of us who have attained years of discretion have been asked the question in our earlier days, which was the heavier, a pound of lead or a pound of feathers. Here, in a glass case, is a bag of feathers (eiderdown), and a weight exactly balancing them. Call the weight a pound of lead, and then truly the pound of lead is balanced by the pound of feathers. Now, the scale beam is a delicate one, and accurately poised. By this pipe is admitted hydrogen gas into the case, the upper part of the case is closed, the hydrogen ascends, the air gradually escapes at the bottom, the scale-beam loses its equilibrium, and the bag of feathers descends, and is evidently heavier than the pound of lead.

This must for the present suffice to satisfy you that weight, as such, must not be considered an accurate measure, and that, somehow or another, a measure for mass must be obtained and used in the place of that which we call weight. These three units then—mass, space, and time—are sufficient for all purposes of measurement, and when reliable data have been furnished from whence these can be deduced, determined, and (if lost) restored, we shall be in possession of all that is required for the purpose of recording every measurement requisite for estimating and comparing the work done by the energy manifested by any one or more of the forces derived from "the imponderables."

(To be continued.)

ON SOME FORMS OF LABORATORY APPARATUS.

By WOLCOTT GIBBS, M.D.

EVERY chemist knows how difficult it is to conduct an evaporation quantitatively in a porcelain or platinum crucible heated from beneath. The following simple contrivance which I devised some years since, and which

has long been in successful use in many laboratories in this country, deserves I think to be more widely known. It consists, as shown in the figure, of a hollow ring of metal, which can be moved up and down upon a vertical rod, also of metal, and which is provided with two stop-cocks, by means of which air and gas may be admitted to the interior of the ring in proper proportions. The ring

has a series of fine openings so placed that the little blue jets of burning gas point radially toward its centre. The common water-blast may be employed with great advantage to give a continued supply of air; and, when the proper proportions of air and gas are obtained, which requires but an instant, the little tongues of blue flame remain constant for hours. A foot-bellows may also be employed when necessary. The crucible to be heated is supported upon the bottom of an inverted Beaufay crucible. The ring-burner is then adjusted so that the points of the little jets of flame play upon the upper edge of the crucible to be heated. After a short time the ring-burner may be lowered so as to heat a lower zone of the crucible, and so on until the outer rim of the bottom is ignited. In evaporations the ring must be more slowly lowered. With a very little practice solutions even of sodic chloride may be evaporated to perfect dryness without loss by decrepitation. Loss by the creeping of solution over the edges of the crucible is also prevented completely. In short, very numerous operations may be performed with the ring-burner more easily, quickly, and safely than by any other form of apparatus with which I am acquainted.

Another petty contrivance, which I find of great service, consists simply of a circular disc or meniscus of porous earthenware. In crucible ignitions, in which a current of gas is passed over the ignited substance—as, for instance, in reducing metallic oxides in hydrogen—great care must be taken to prevent mechanical loss. In such cases I place a porous capsule in the crucible above the substance to be heated, as in the figure. The gas may then be

introduced through the perforated cover by means of a porcelain pipe in the usual way, and passes through the porous capsule by diffusion. Mechanical loss is thus completely prevented, as the soft capsule may readily be filed so as to fit the crucible accurately.*

My acknowledgments are due to Mr. W. E. Cutter for his most efficient aid in the prosecution of my work.

CORRESPONDENCE.

ON BUTTER.

To the Editor of the Chemical News.

SIR,—I entirely agree with "J. B." in his desire for the continuance of such useful papers as the "Testing of Butter." I have been a regular subscriber to your journal for some years, and would give such thoroughly practical and really useful articles a hearty welcome.

Without expressing any opinion whatever on the paper itself, I must say it is not fair to criticise any production in a sweeping manner. Mr. Wanklyn has certainly done his best to merit "silent contempt" from his opponent; but I trust Dr. Brown will reply, without noticing the satirical strain of the critique, and defend his position as a public analyst.—I am, &c.,

W. F. CATCHSIDE.

Snodland, near Rochester.
July 16, 1873.

* As an example of the utility of this little apparatus, I may refer to Mr. R. H. Lee's paper on the atomic weights of cobalt and nickel. *Am. Jour. Sci.*, vol. ii., July, 1871.

ON BUTTER.

To the Editor of the Chemical News.

SIR,—It appears to be necessary to inform Mr. Wanklyn that the glycerides of palmitic acid, butyroleic acid, butyric acid, &c., which are stated in the second paragraph of the paper on "Butter" (*CHEMICAL NEWS*, vol. xxviii., p. 1) to be the chemical constituents of butter, are the substances which Mr. Wanklyn calls palmitin, olein, butyryn, &c., in his courteous letter (vol. xxviii., p. 18).

Stearin can sometimes be obtained from butter, and sometimes not; but it does not occur in butter as crystallised stearin. When butter is fused at a low temperature the globules are still found on cooling. When it is fused at a high temperature they are not found on cooling; but the butter then has an imperfect crystalline structure, has lost its smoothness, and is very much depreciated in value: it does not exhibit crystals of stearin like those of lard and the mixture of refined fats known as "beurre de Paris," when examined by the microscope with polarised light.

No one is more sensible than I am of the imperfections of the scheme for examination of butter to which Mr. Wanklyn refers, yet I believe it is slightly better than any which has previously been published. When its results are negative, it does not prove the butter to be pure; when its results are positive, I believe they are reliable.

Mr. Wanklyn also has been working on butter; doubtless he could produce a much better method for proving admixture of refined fats with butter. Would it be too much to ask him to do so? Perhaps you, sir, would readily afford him the needful printers' ink.—I am, &c.,

J. CAMPBELL BROWN.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Under this heading will be found an encyclopaedic list of chemical papers published abroad during the past week, with abstracts of all susceptible of advantageous abridgment. The two half-yearly volumes of the CHEMICAL NEWS, with their copious indices, will, therefore, be equivalent to an English edition of the "Jahresberichte."

NOTE. All degrees of temperature are Centigrade, unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances de l'Académie des Sciences, June 23, 1873.

Second Note on Guano.—M. Chevreul.—In this paper the author does not give the results of a substance forming long acicular crystals, but treats of the gas disengaged by the action of water upon hard portions of guano, and of a vitreous substance taken from a sample of guano at Havre. The gas in question proved to be carbonic acid. The glassy substance had a strong ammoniacal odour mingled with that of avic acid, and consisted mainly of phosphate of ammonia. Returning to the consideration of the ultimate analysis of manures as commonly practised for commercial purposes, the author remarks that he can conceive the utility of the present system if applied to the comparison of two samples of guano; but that he cannot conceive it at all when, e.g., a guano is to be compared as to its agricultural value with shoddy, bones, hair, or analogous substances. He insists especially on the power which guano possesses of giving off—when in contact with water—free carbonic acid simultaneously with the production of carbonate of ammonia. He contends that the peculiar odour of "avic acid" becoming more perceptible after that of ammonia

has disappeared, may serve as an indication as to the origin of alleged guano.

Researches on Chlorine and its Compounds.—M. Berthelot.—A thermo-chemical paper, bearing upon the controversy existing between the author and Prof. Thomsen. M. Berthelot details experiments on the behaviour of chlorine with water and with metallic proto-salts, showing what conditions the employment of chlorine in thermic measurements ought to fulfil, and throwing light on the *modus operandi* of chemical affinities. He examines the action of chlorine on water, on mercurous chloride, stannous chloride, and ferrous sulphate.

On Blast-Furnaces.—M. L. Gruner.—The author concludes—(1) That the yield of large blast-furnaces, beyond the bulk of 200 cubic metres does not increase proportionally to their capacity. (2) That up to a certain limit, variable with the state of the ore and of the fuel, there is an advantage in increasing the height of these furnaces, but that beyond this limit nothing is gained by an augmentation either of height or capacity. (3) That the minimum consumption corresponds to a mean speed of the general descent of the charge; that is to say a deficiency and an excess of the blast both equally lead to an increased consumption. In both cases there is a departure from the optimum progress of the furnace. (4) That the heat introduced by the hot-blast advantageously replaces that furnished by direct combustion near the tuyeres, but that the relative economy diminishes as the temperature rises higher. Beyond 700° and 800° the real economy becomes inconsiderable.

Production of Methylic Alcohol in the Distillation of Formiate of Lime.—C. Friedel and R. D. Silva.—The authors, previous to the publication of the memoir of Lieben and Paterno on the same subject, had announced to the Chemical Society (Paris) in its session May 2, 1873, that the dry distillation of the lime salt of a new valerianic acid, mixed with an excess of formiate of lime, yielded methylic alcohol. The same alcohol was also obtained by distilling the pure formiate. Formic aldehyde was probably simultaneously produced, the characteristic odour of dioxymethylen being distinguishable. During the decomposition of the formiate a considerable quantity of a gas was produced, one portion of which was absorbed by the chloride of iodine forming an oily product, doubtless chloriodide of ethylen and propylen; the portion not absorbed consisted of hydrogen. The fact above pointed out is a further instance of the analogy between those reactions which are called pyrogenous and those which take place at low temperatures: the nascent hydrogen behaves alike in both cases, and is capable of transforming by its fixation the aldehydes into alcohols.

On Tereben.—J. Ribau.—The author shows that the body commonly known as tereben is a mixture of cymen and of true tereben, the latter of which he has succeeded in isolating. It is a colourless liquid, mobile, of a faint peculiar odour. It does not congeal at -27°, and is less oxidisable than its isomer terebenthen. It boils at 155° to 156° at a pressure of 760 m.m., and its rotatory power is 0. Its composition is—

Carbon	88.24
Hydrogen	11.76

100.00

and its formula $C_{10}H_{16}$.

Production of Rotatory Power in the Neutral Derivatives of Mannite.—M. G. Bouchardat.—The author considers that the most natural interpretation of the facts he has observed is that mannite, a substance inactive in itself, and in which no known fact warrants us in admitting any rotatory power, by what process soever it may have been obtained or regenerated, cannot be split up into several optically active substances, but acquires in its combinations with acids, or by the fact of dehydration,

the power of acting upon the polarised ray. There seems thus to be a creation of rotatory power by the fact of combination.

New Researches on the Electric Effluve.—MM. Thenard.

New Series of Observations on the Solar Protuberances; New Researches on the Relation between Protuberances and Spots.—P. Secchi.—The author tabulates observations during four months, from Jan. 1 to April 22, thus completing two years. The spots and protuberances have diminished in number and size from a maximum in February to an absolute minimum observed in May, when the sun was several days without spots, and the protuberances were only five or six (being like woolly masses and without filaments). At time of writing (June 9), the activity was renewed. The author corrects M. Respighi's supposition that his interpretation of the absence of the chromosphere on the spots was only based on drawings; he was guided by direct observations. The question is, whether at these points the matter retires or advances; according to P. Secchi, it advances (*sorts*). He has further experimented with the electric light and the absorbent power of metallic vapours. Projecting the solar spectrum on the light produced by sodium in combustion, he obtained a diffusion of the lines D_1 , D_2 , just as in the spots. The lines not only became broader, darker, and more diffuse, but a dark shade extended to right and left to a distance about twenty times that of the two lines. This shade he has also obtained with the spots. With iron and the electric light from a pile of fifty elements, he did not succeed in distinguishing the line 1474 K, though he counted more than 480 lines. Magnesium with the electric light gave lines greatly broadened and nebulous at the edge, and nearly touching each other, as had also been observed in a solar eruption of exceptional violence. Some lines in the blue he supposed to be from oxide of magnesium.

Influence of Atmospheric Refraction, relative to the Instant of Contact in the Transit of Venus.—M. Ed. Dubois.—A mathematical paper, with cuts.

Colouration and Greening of Neottia Nidus-Avis.—M. Ed. Prillieux.—This plant, of the family of Orchids, forms an exception to the rule that nearly all the phanerogams, having no chlorophyll, are parasites. Some time since, Herr Wiesner found that when the plant was kept in alcohol it took a green colour, which it afterwards gave up to the liquor. Hence he inferred that the exception was only apparent, the brown plant really containing chlorophyll, which, though masked, played the same part as in green plants. M. Prillieux finds that the little crystalline bodies of proteic matter, which form the brown colouration, are deformed when bathed in certain liquids, and that some liquids change both form and colour, producing the green colour. Not only solvents of chlorophyll (such as alcohol, ether, benzin), but acids (such as hydrochloric, sulphuric, nitric) and alkalies (as potash) are capable of producing the green; heat also. A slip of *Neottia Nidus-avis* put in boiling water soon turns green. If the greened plant be put in a liquor capable of dissolving chlorophyll, the characteristic properties of chlorophyll (optical, spectroscopical, &c.) may be observed. The author asks whether the chlorophyll pre-exists in the brown crystalline substance in the living plant. From some experiments he made, the conclusion seemed natural that it does not, but that when the crystalloids become green, the fact is that their substance itself is transformed into chlorophyll; not that a foreign matter, mixed with chlorophyll, is destroyed, and ceases to mask it. But he does not consider the point fully decided.

Semi-Diurnal Variations of the Barometer.—M. Broun.—These have been explained by currents of air rising from equatorial regions and going towards the poles. The writer cites some observations he made in Malabar and Coromandel, and which are against this view. Thus, in the fine season, when the semi-diurnal oscillation of

the barometer at Malabar is greatest, there is perfect stillness at 6000 feet above the sea throughout entire days. Two facts must be recognised in theorising on the variation. One is, its change with the season in Europe. It is greatest in winter, and smallest in summer. In winter, the morning minimum is more marked; in summer, the evening. The variation during the day in summer resembles that during the night in winter, and *vice versa*. The other fact is, the change of the variation with height above the sea. From observations made by the author in India, it appears that, the nearer one approaches constant atmospheric conditions, the more nearly do the proportions between amplitude of semi-diurnal variation and total pressure approach a constant value. For places where there are not high plateaus, it may be said that, from 6000 feet, the oscillations are proportional to the total pressure for each station. The conclusions arrived at are—that the thermal hypothesis is to be rejected, and that the facts accord with the hypothesis of a polar attraction of the sun.

Study on Apparatus for Heating with Hot Air.—M. Ducrot.—From the theoretical point of view, the writer concludes that the quantity of calories furnished by the same apparatus, acting under the same conditions, is greater as the heated air issues at a lower temperature. By the same conditions, he means a constant external temperature, same quantity of fuel disposed in the same manner on the grating, burned in the same time with equal quantities of air. There is, however, for a piece heated with a given weight of fuel per hour, a maximum of temperature corresponding to a determinate quantity of air passing over the heating apparatus.

On the Determination of Phosphoric Acid in all Products of Agricultural and Physiological Importance.—M. H. Joulie.—This paper, the conclusion of M. Joulie's interesting memoir, is not available for abstraction, but will be inserted in full at an early date.

Theory of Tanning.—M. A. Reimer.—A lengthy and exhaustive paper which we shall also endeavour to give in full.

On Perfumes, from a Physiological and Commercial Point of View.—James Paton.—A memoir read

before the North British Branch of the Pharmaceutical Society.

Toxicological Detection of Phosphorus.—We extract the following from a notice of Dragendorff's "Manual of Toxicology":—The detection of phosphorus can be effected by two methods: we either seek to isolate it as such, or at least to exhibit its luminous properties; or, we endeavour to find its products of oxidation other than phosphoric acid (which, of course, is naturally present in the animal body. Mitscherlich's procedure is based upon the isolation of the phosphorus by distillation and the exhibition of its peculiar light. The suspected fluids are diluted, if needful, with water, and the homogeneous mixture introduced into a flask of sufficient size. Sulphuric acid is then added. The flask is closed with a cork, through which passes a tube bent twice at right angles, 2 or 3 centimetres in diameter and 5 or 6 long, and communicating with a Liebig's condenser of glass. Heat is then applied to the flask, and the process of distillation carried on in a darkened room. Luminous vapours appear in the flask as soon as the liquid is in ebullition. These vapours gradually ascend the tube, and become almost permanent at the spot where the first drops of watery vapour condense. Fresenius and Neubauer have recognised these luminous vapours for half an hour with a solution containing 1 milligram of phosphorus diluted to 200,000 parts. Huseman and Marmé introduced 1 c.c. of phosphuretted oil into the stomach of a rabbit, and obtained distinct luminous indications from the contents of the stomach, the animal having been killed five hours afterwards. The distillate may contain granules of phosphorus even when none can be recognised in the matters submitted to distillation. The process, however delicate, is not applicable in all cases. Certain products of putrefaction, creosote, sulphuretted hydrogen, alcohol, ether, and oil of turpentine prevent the appearance of the luminous vapours. The phosphorus may always be detected when in quantity sufficient to separate out in granules, but the presence of these foreign bodies may mask mere traces. In such cases the distillate is subjected to a further examination. Scheerer recommends to distil in a current of carbonic acid gas, in order to prevent any of the phosphorus being lost by oxidation. By this method, however, the valuable character of luminosity is sacrificed. It may happen that all, or most of the phosphorus, has been transformed into phosphorous or hypophosphorous acid, in which case little or no luminous vapour can be detected by the above-mentioned method. The vapours of phosphorous and hypophosphorous acids reduce salts of silver, and consequently blacken filter-paper saturated with an argentic solution. This reaction is so sensitive that when it fails we may be sure of the absence of phosphorus. The converse unfortunately does not hold good, since many bodies produce a similar reaction, e.g., formic acid and sulphuretted hydrogen. Hence Scheerer recommends the simultaneous employment of paper soaked in acetate of lead, which is blackened by sulphuretted hydrogen, but not by the acids of phosphorus. Fresenius and Neubauer have shown that ozone may give a brown colour to the lead-paper. It is, therefore, better to replace the lead with other test-papers prepared with nitro-prusside of sodium, arsenious acid, and chloride of antimony. The simultaneous colouration of these papers will show the presence of sulphuretted hydrogen, but will prove nothing as to the simultaneous presence or absence of the phosphorus acids. Scheerer proposes to search for phosphorus in the silver paper. It is to be washed with boiling water, the silver separated with hydrochloric acid, and phosphoric acid determined in the filtrate by means of molybdate of ammonia. It is better to dissolve the filter-paper in aqua regia. The only drawback to this process is the difficulty of procuring filter-paper absolutely free from phosphates. Dussard and Blondlot treat the homogeneous mass under examination with pure zinc and sulphuric acid. The gas generated contains phosphides of hydrogen, and burns with a characteristic green flame. The gas, before being

burnt, is freed from every trace of sulphuretted hydrogen by being passed through tubes filled with pumice steeped in potassa-lye. It should be burnt at a platinum orifice, for the yellow colouration of soda in the glass would otherwise mask the reaction. The hydrogen must not be mixed with arseniuretted or antimonuretted hydrogen. The presence of alcohol, ether, and other organic matters is fatal to the reaction. The green colour is more distinct by daylight than in a darkened room. Blondlot has remarked that the phosphuretted hydrogen disengaged gives a black precipitate, phosphide of silver, in solutions of nitrate of silver. The phosphide, placed in a suitable apparatus with zinc and hydrochloric acid, gives off a gas which burns with a green flame. In this manner he removes the organic matters which interfere with Dussard's procedure. The following is his method:—The suspected matters are converted into a homogeneous paste, and introduced into a roomy hydrogen apparatus with zinc and sulphuric acid. The gas is passed through a solution of nitrate of silver. The precipitate is filtered off, when it no longer increases in bulk, washed, and introduced into a small apparatus, and treated as above. This process occasions the loss of a part of the phosphorus. Fresenius and Neubauer have proved that merely two-thirds of the phosphorus are thrown down as phosphide of silver. These two chemists combine the two procedures of Mitscherlich-Scheerer and of Dussard Blondlot. They first employ the method of Mitscherlich, or that of Scheerer, according as there appears to be more or less of the poison present. In some cases not merely distinct luminous vapours are seen, but granules of phosphorus are isolated. As soon as these characteristics cease to appear, nitrate of silver is added to the condensed liquid, and the distillation is continued. The well-washed precipitate is introduced into the hydrogen apparatus. The purity of the zinc and sulphuric acid employed should be determined by a previous experiment. Fresenius and Neubauer have analysed a liquid (putrid blood and water), containing 1 milligram of phosphorus in 200,000. The first 400 c.c. of hydrogen presented the most characteristic reactions. The colouration was more feeble with the 400 next, and very faint but still perceptible with the 400 last. Christoffe and Beilstein recommend the examination of the flame with the spectro-scope. The residue of the distillation may contain phosphorous acid formed by the oxidation of the phosphorus. It may be treated with zinc and sulphuric acid. Phosphoric acid is never decomposed in these conditions. The contrary is the case with the hypophosphites, which, being latterly employed in medicine, may be the cause of errors.

Clarification of Beer by means of Tannin.—E. Brescius.—For 1000 litres the author employs about 140 grms. of tannin, dissolved in 0.75 litre of water, which is thoroughly stirred up. After three or four days he adds 1 litre of isinglass or 2 of gelatine in the proportion of 1 kilo. to 100 litres. The complete clarification requires about eight days.

On a New Method of Dyeing and Printing with Indigo.—P. Schutzenberger and F. de Lalande.—The energetic reducing action of hydrosulphite of soda, and its almost instantaneous influence upon indigo, which it converts in the cold into white indigo, has led the authors to study the practical employment of this salt in the various applications of indigo in dyeing and printing. The vats most commonly employed in modern times are the copperas vat for vegetable fibres, and the fermentation vat for wool. The chief inconvenience of the former is the presence of a bulky precipitate of oxide of iron and of sulphate of lime, which have to settle before the clear liquid can be used for dyeing. Fermentation vats are difficult to manage, and liable to sudden changes, which may in a few hours involve the loss of all the indigo contained. The hydrosulphite vat which the authors propose, as well for animal as vegetable fibres, is set as

follows.—Bisulphite of soda, standing at 30° to 35° Baumé, is brought in contact in a covered vessel with twisted sheet zinc or granulated zinc, filling up to the top of the vessel without occupying more than one-fourth of its real volume. After the lapse of about one hour the liquid is poured into an excess of milk of lime, which precipitates the salts of zinc. It is stirred, and the clear liquid drawn off either by filtration and pressure, or by decantation after the addition of water. Air should be excluded as much as possible. By mixing the hydrosulphite thus obtained with ground indigo and the amounts of lime or soda needful to dissolve the reduced indigo, we obtain at once a yellowish liquid containing no insoluble matter except the earthy impurities of the indigo. One kilogramme of indigo may be thus reduced so as to form a solution not exceeding 10 to 15 litres in volume. For dyeing, a certain quantity of the reduced indigo solution is run into a vat filled with water. This vat being clear in its entire depth, the operation of dyeing involves no loss of time. The excess of hydrosulphite constantly reduces the scum of oxidised indigo forming on the surface of the dye-bath, the strength of which can be kept up during working by successive additions of the concentrated indigo solution. Thus the required shade can be obtained with the smallest possible number of dips. This vat gives shades more solid and clear than can be obtained with the old vats, and enables the dyer to produce upon wool very light blue bottoms, which are ordinarily got by means of sulphate of indigo, and are in consequence much more fugitive. The process at present employed for printing indigo-blues consists in printing on white indigo, or indigo-talc of tin, obtained by precipitating a tin vat with hydrochloric acid, or by adding to the clear portion of a copperas vat a mixture of tin-salt and hydrochloric acid. The precipitate, thickened with gum, is printed on the calico, and then fixed with milk of lime. The goods are next passed through a chloride of lime bath, sulphuric acid, and soap. The process is difficult, delicate, and costly. Various attempts at improvement have hitherto failed in securing complete success. We may mention as examples the faience blue, pencil blue, and printing with a concentrated vat in an atmosphere of coal gas, air being excluded. The authors propose to print with an alkaline solution of reduced indigo, suitably concentrated and thickened, containing a large excess of hydrosulphite of soda. The presence of this salt tends to keep the indigo-blue reduced which otherwise tends to become oxidised during the time of printing. This part of the process can be carried out in common air, and with an ordinary machine, the oxidation being so slight that after an hours' work the remnant of the colour is still yellow and soluble. By thus printing on reduced indigo immediate fixation is secured, and entire colouring matter is utilised. Experience has proved that, for equal shades, 50 to 60 per cent less indigo is consumed with the new process than with the old. The shades obtained are more beautiful and solid, and the impression is better defined. The new indigo blue, requiring no subsequent fixing process, can be printed along with a great number of other colours, such as aniline black, garancin, colours obtained by dyeing or steaming, catechu shades, chrome colours, colours fixed with albumen, &c. Thus new styles may be created which would be difficult to execute in any other manner. The blue printing colour is formed by thickening with gum or any other suitable material, a sufficiently concentrated solution of white indigo in an alkali, and adding to the mixture a sufficient quantity of hydrosulphite of soda. After printing, the pieces are hung up for twenty-four hours to oxidise, washed and soaped.

ABRIDGMENTS OF PROVISIONAL AND COMPLETE SPECIFICATIONS.

Improvement in the manufacture of the phosphates of soda and potash, and chloride of ammonium; also in the manufacture of chemical manures and alkalis. Robert Storr Best, Goole, Yorkshire. December 5, 1872.—No. 3687. I take phosphoric acid, derived either from aluminous phosphates after the extraction of alum, or from other sources, and in definite proportions mix with potassium or sodium chloride, then saturate with ammonia, either from distillation of gas-water, or the destructive distillation, with lime, of wool refuse, leather, horn shavings, or other nitrogenous substance. I then evaporate to crystals or dryness, and use the product at once as a highly concentrated manure, or recover the ammonium chloride by crystallisation or sublimation, leaving the potassium or sodium phosphate to be dealt with. I then form a solution of the alkaline phosphate, precipitate tribasic phosphate of lime, by the addition of lime to the solution, having potash or soda remaining, which I evaporate to dryness. I then treat the precipitated phosphate with a further quantity of phosphoric acid, forming monobasic phosphate, dry by mixture with calcined gypsum or salt of magnesia, and thus produce a very concentrated superphosphate of lime.

An improved apparatus for drying sewage precipitates, cement, paper pulp, and other fluid or semi-fluid matters. William Hart and James Hart, Crossness, Kent. December 9, 1872.—No. 3734. This apparatus consists essentially of a revolving drum (the cylindrical part of which is perforated or reticulated) and other apparatus in connection therewith, such drum and apparatus being arranged as hereinafter described so as to separate the water from the matter to be dried and draw a coating of such matter on to the periphery of the drum, then to draw hot air through the coating to dry it, and then to force cold air through the dried matter to detach it. The drum consists of two discs mounted on a horizontal shaft, wire gauze being affixed to the edges of the discs to constitute strainers. The lower part of the drum works in a tank containing the matter to be dried. The upper part (except at the part where the dried matter is detached) is covered by a hot air casing into which hot air is introduced by a pipe leading from the heater to a trough affixed to the casing. The drum is divided into a series of longitudinal chambers which communicate with ports in a cylinder keyed on the drum shaft and outside the drum. This cylinder revolves in a stationary outer cylinder of such a diameter as to leave an annular space between the two cylinders. This annular space is divided into three chambers, termed respectively the water exhaust chamber, the hot air exhaust chamber, and the blast chamber. The water exhaust chamber communicates with a suction pump which draws the water through those of the chambers which are immersed in the matter to be dried, and causes a coating of such matter to adhere to the drum. The water drawn into the chambers is drawn therefrom through pipes and ports which communicate with the water exhaust chamber. The hot air exhaust chamber communicates with a suction pump which draws hot air through those of the longitudinal chambers which are passing under the hot air casing, and thereby dries the coating of matter on the drum. The blast chamber communicates with a forcing pump which forces air through the longitudinal chamber in communication with the said blast chamber, which air tends to loosen or detach the dried matter from the drum. A brush or scraper is mounted on this part of the drum to complete the removal of the matter.

An improved insulating compound for telegraphic purposes. William Robert Lake, of the firm of Haseltine, Lake, and Co., patent agents, Southampton Buildings, London. (A communication from Zalmon G. Simmons, Kenosha, Wisconsin, U. S. A.) December 9, 1872.—No. 3735. This invention relates to a composition of materials in producing an insulating compound by means of which a more perfect insulation of telegraphic conductors is obtained than by the ordinary means; this compound is at the same time cheap and durable, and is not easily affected by the action of the weather. This compound is composed of one part coal-tar or its equivalent, and two parts charcoal or saw-dust, tan bark, or any other organic body having a fibre and being a poor conductor of electricity, and which may be ground or cut up to mix with the tar. The coal-tar is brought to a boiling temperature when the charcoal is introduced and thoroughly combined with it by agitating the entire mass by any mechanical means. The proportions may be varied.

An improved method of clarifying and settling varnishes, oils, and other like substances. William Robert Lake, of the firm of Haseltine, Lake, and Co., patent agents, Southampton Buildings, London. (A communication from Franklin Kersting, Grand Rapids, Michigan,

U. S. A., grainer and polisher). December 9, 1872.—No. 3737. I take oyster shells, burn them well, and grind them to a fine powder. I then grind marble chips and dust to a powder also. These are thoroughly mixed together and thrown into a vessel containing the liquid. The mixture is then allowed to stand forty-eight hours, during which time all the dirt, motes, and gum specks of the liquid are precipitated to the bottom of the receptacle, and a new and improved varnish or article is thus produced for the trade.

Improvements in the treatment and utilisation of sewage water. Henry Young Darracott Scott, Ealing, Middlesex, Major-General, C.B. December 11, 1872.—No. 3755. The objects of this invention are, economy in dealing with sewage, the effectual cleansing of the drains, and the preventing the generation of noxious sewer gases.

*A new or improved motive-power engine actuated by soluble gases.** William Edward Gedge, patent agent, 11, Wellington Street, Strand, Middlesex. (A communication from Georges Thomas de Kercado, 64, Faubourg St. Martin, Paris). December 12, 1872.—No. 3766. This invention relates to a motive-power engine actuated by soluble gases, such as chlorhydric acid gas, ammoniac or metillic gas, or any gas having the property of dilating at a low temperature and condensing with equal facility. The soluble gas separates itself in a heated generator from the liquid which had dissolved it, and passes into a reservoir, from whence it is distributed to the cylinders, after acting upon the pistons of which it passes into a condenser, there re-uniting with the absorbing liquid, which, forced by the gas from the generator, has passed through a jacket surrounding the gas-reservoir, and from thence to the condenser. After complete absorption of the gas by the liquid, the solution made in the condenser goes to a receiver, and from thence to the generator, where the separation again takes place, the gas and liquid again make the same circuit, and so on indefinitely.

Improvements in the means and apparatus for conveying sewage and other liquid or partially liquid refuse from cesspools, privies, and other receptacles. Charles Denton Abel, 20, Southampton Buildings, Chancery Lane, Middlesex. (A communication from Alexander Frederick Booroff, St. Petersburg, Russia). December 13, 1872.—No. 3768. This invention relates to the arrangement, construction, and operation of apparatus for emptying cesspools and receptacles of excreta and other refuse and conveying the contents by pipes to localities where they may be discharged or utilised without permitting the escape of offensive emanations. For this purpose a system of pipes provided with valves is arranged underground communicated with the cesspools and other receptacles for sewage and other refuse, and leading to a discharging apparatus consisting of a well or shaft in which is a vertical stand pipe communicating with the system of pipes and with an air-pump or other apparatus for producing a vacuum. By the action of the stand pipe and the exhausting apparatus the sewage is made to flow down into the well, whence it is removed by a dredging machine or chain buckets. At the highest points of the sewer pipes closed reservoirs are connected thereto, in which the foul gases accumulate, and from which they are conducted to burners for consuming them. The sewer pipes are connected with the water mains for the purpose of filling them with water at starting, and for flushing the pipes when required.

Improvements in the manufacture of hydrogen gas. James Frederick Lackersteen, civil engineer, 3, Lombard Court, London. December 17, 1872.—No. 3829. The specification of this invention describes a method of manufacturing hydrogen gas by passing steam, superheated or otherwise, through or over heated manganese, or any suitable compound thereof, by which means the steam is decomposed, the oxygen being absorbed by the manganese, and the hydrogen set free, to be conveyed away by suitable means, and used for whatever purpose it may be required.

NOTES AND QUERIES.

Lemon-Chrome.—(Reply to L. C.)—I think if L. C. adds a little potassic carbonate to the chromate before mixing with the lead solution it will give the desired shade. Perhaps the chromate of potass used was not quite neutral; this would render it so.—H. C.

Chrome Yellow.—Can any of your readers inform me what substitute can be used for nitrate or acetate of lead to precipitate bichrome of potash yellow? The Germans are now making a yellow pigment without using lead, and if you can put me upon the track I shall feel obliged.—COLOUR.

Anthracen.—I shall feel greatly obliged if any of my fellow readers will inform me of a good reliable method for estimating the percentage of anthracen in commercial samples. I am acquainted with the method by use of methyl-alcohol, but experience great difficulty in purifying very crude samples. Also, if I could be informed of the colour of pure anthracen, and correct fusing-point I should be obliged.—D. W.

Safety at Sea.—The recent sudden destruction of two large passenger ships, the *Atlantic* and the *City of Washington*, has called attention to the desirability of availing ourselves of the means which modern science has placed at our command for the prevention of such disastrous accidents. For this purpose, each large passenger ship should carry a small, but powerful steamboat or launch, and in foggy weather this steam launch should be sent on ahead some few hundred yards, being connected with the passenger ship by a flexible telegraphic cable provided with an electric battery, so that signals or messages might be continually transmitted from one to the other. The steam-launch should also carry an electric or other strong light, and be provided with a powerful steam whistle. On meeting with ice or with vessels, or unexpectedly approaching the coast, it would be comparatively easy to stop the steam-launch and give warning in time to save the passenger ship from danger.—JOHN NEWLANDS, F.C.S.

Prussiate of Potash: Oxalic, Tartaric, and Citric Acids, and Appendices containing the latest information and specifications relating to the materials described in Parts 3 and 4.

BAILLIERE AND CO., 20, King William Street, Strand.

Analysis of Food, Water, and Air.—Mr. WANKLYN has opened a Laboratory at 117, Charlotte Street, Fitzroy Square, and is prepared to give Practical Instruction in Chemical Analysis to Medical Officers of Health, and to persons proposing to undertake the duties of Public Analysts under the new Act.

BERNERS COLLEGE of CHEMISTRY.—EXPERIMENTAL MILITARY and NAVAL SCIENCES, under the direction of Professor E. V. GARDNER, F.R.S., &c., of the late Royal Polytechnic Institution and the Royal Naval College.

The Laboratory and Class Rooms are open from 11 to 5 a.m., and from 7 to 10 p.m. daily.

Special facilities for persons preparing for Government and other examinations.

Private Pupils will find every convenience.

Analyses, Assays, and Practical Investigations connected with Patents, &c., conducted.

For prospectus, &c., apply to Prof. E. V. G., 44, Berners-street, W.

North London School of Chemistry, Pharmacy, &c.—Conducted by Mr. J. C. BRAITHWAITE, for thirteen years Principal Instructor in the Laboratories of the Pharmaceutical Society of Great Britain, and Demonstrator of Practical Pharmacy, Pharmaceutical Latin, &c.

The Session 1872-1873 will commence on the 1st of October when—

The LABORATORY will be open at 10 a.m. for Instruction in Practical Chemistry as applied to Pharmacy, Medicine, Analysis, &c. Terms moderate.

The CLASSES will meet as usual.

The CHEMICAL and TOXICOLOGICAL CLASS on Monday and Thursday evenings at 8 p.m., commencing October 1st.

The LATIN CLASS on Tuesdays and Fridays at 8 p.m., commencing October 2nd.

The MATERIA MEDICA and BOTANICAL CLASS, every Wednesday and Saturday at 8 p.m., commencing October 3rd.

The BOTANICAL GARDEN affords to Students desirous of acquiring a Practical Knowledge of Botany every facility for doing so. During the Season BOTANICAL EXCURSIONS are made every Saturday at 10 a.m.

Fee to either of the above Classes Half-a-Guinea per Month. Pupils can enter at any period to either Classes or Laboratory.

All Fees must be paid in advance.

PRIVATE TUITION for the usual Examinations of the Society, the Modified Examination, &c.

Letters of inquiry should be accompanied with a stamped envelope.

Address—54, KENTISH TOWN ROAD, N.W.

LIEBIG COMPANY'S EXTRACT of MEAT.

—None genuine without the Inventor's facsimile in blue being on the Trade-mark label and outer cover. Pure condensed Essence of Beef Tea, excellent economic flavouring stock for soups, sauces, and made dishes.

"Food for the nerves." (Liebig).

Methylated Spirits.—David Smith Kidd, Licensed Maker, Commercial Street, Shoreditch, N.E. Also FINISH, FUSEL OIL, and RECT. NAPHTHA.

Water-glass, or Soluble Silicates of Soda and Potash, in large or small quantities, and either solid or in solution, at ROBERT RUMNEY'S, Ardwick Chemical Works, Manchester.

THE LIVERPOOL COLLEGE OF CHEMISTRY, 96, DUNE STREET, LIVERPOOL. Specially Devoted to the Study of CHEMISTRY, TECHNOLOGY and ASSAYING.

Laboratories open throughout the Year.

MARTIN MURPHY, F.C.S., &c., Principal (Successor to the late Dr. SHERIDAN MURPHY).

A Special Laboratory is devoted to Commercial Analyses of every description, and to Mineral Assays.

Manufacturers' and Smelters' Analyses and Assays undertaken on Contract.

Patentees and Inventors Advised and Assisted. Works and Mines Inspected. The Erection of Manufacturers' Plant Supervised, &c.

Terms and Fees VERY MODERATE.

Further Particulars and Full Prospectus on application to The Principal, MARTIN MURPHY, F.C.S. &c.

ESTABLISHED 1798.

MANUFACTURERS OF
HYDRATE OF CHLORAL.

OXIDE OF IRON.

We are prepared to supply, on moderate terms,

HYDRATED PEROXIDE OF IRON (BOG OCHRE), Same quality as supplied by us to several of the most extensive Gas Companies, and which has given entire satisfaction.

FRANCIS RITCHIE AND SONS, BELFAST.

THE CHEMICAL NEWS.

Vol. XXVIII. No. 743.

THE POLLUTION OF RIVERS BILL.

THE Earl of Shaftesbury has presented to the legislature a Bill, bearing the above title, and embodying the water-clauses, which were struck out of the Public Health Bill before it became law last session.

As will be remembered, serious objections were raised against that portion of the Public Health Bill which relates to the Pollution of Rivers, and Mr. Stansfeld was so convinced of its impracticability that he publicly repudiated it, and excused the Government at the expense of the Rivers' Commission.

On behalf of the great majority of English chemists we protest against the resuscitation in the House of Lords of recommendations of the Rivers' Commission, which were expunged from the Public Health Bill, and repudiated by a responsible minister of the Crown.

These recommendations are as follows. We quote them from the printed draft of the Earl of Shaftesbury's Bill, which lies before us.

"Clause 7. For the purposes of this Act the following liquids shall be declared to be polluting (that is to say):—

"(1). Any liquid containing in suspension more than 3 parts by weight of dry mineral matter, or 1 part by weight of dry organic matter, in 100,000 parts by weight of the liquid:

"(2). Any liquid containing in solution more than 2 parts by weight of organic carbon, or 0.3 part by weight of organic nitrogen in 100,000 parts by weight of the liquid:

"(3). Any liquid which exhibits by daylight a distinct colour when a stratum of 1 inch deep is placed in a white porcelain or earthenware vessel:

"(4). Any liquid which contains in solution in 100,000 parts by weight more than 2 parts by weight of any metal, except calcium, magnesium, potassium, and sodium:

"(5). Any liquid which in 10,000 parts by weight contains, whether in solution or suspension in chemical combination or otherwise, more than 0.05 part by weight of metallic arsenic:

"(6). Any liquid which, after acidification with sulphuric acid, contains in 100,000 parts by weight more than 1 part by weight of free chlorine:

"(7). Any liquid which contains in 100,000 parts by weight more than 1 part by weight of sulphur in the condition either of sulphuretted hydrogen or a soluble sulphuret:

"(8). Any liquid possessing an acidity greater than that which is produced by adding 2 parts by weight of real muriatic acid to 1000 parts by weight of distilled water:

"(9). Any liquid possessing an alkalinity greater than that produced by adding 1 part by weight of dry caustic soda to 1000 parts by weight of distilled water:

"(10). Any liquid exhibiting a film of petroleum or hydrocarbon oil upon its surface, or containing

in suspension in 100,000 parts more than 0.05 part of such oil."

The Bill proposes to punish persons who discharge into streams, liquids answering to the above descriptions. When this matter was under discussion last year the futility of merely estimating the strength of a discharge was pointed out, and it was shown that the effect of such a course would be to put manufacturers to inconvenience and inflict injury upon them. And, as will be remembered, deputations of manufacturers waited on Mr. Stansfeld, to urge upon him the damage which would be done to the industries of the country if the Bill, in its unamended form, came into operation.

We will now take up the subject of the definitions of what constitutes a polluting liquid, and show how injudicious are the above-quoted recommendations, and how impossible it will be to attend to them in practice.

According to the first definition in Clause 7, no liquid must flow into a river if it has suspended in it more than 3 parts of mineral matter in 100,000.

We remind our readers that the Thames sometimes contains 50 parts of suspended matter in 100,000; the Rhine at Bonn 20; the Meuse 47; the Ganges 20 to 200; the Seine 12; and the Mississippi 80. The last river is said to carry down annually to the sea no less than 4000 million cubic feet of clay.

As was pointed out by the Marquis of Salisbury, any ditch draining into a river might entail penalties on landowners, provided the water in the ditches was not purer in this respect than some of the greatest rivers in the world. Indeed, the Bill would entail the penalties on the owner of *one end* of the ditch.

Definition 2, prohibits more than 2 parts of "organic carbon," or 0.3 part of "organic nitrogen" in 100,000 parts of the discharge. Let us examine this.

London sewage consists mainly of the day's excreta mixed with 30 gallons of water per individual. Taking the day's urine to be 3 lbs. (which is rather a high average), it would, therefore, appear that the urine is diluted with 100 times its weight of water, in order to make London sewage. Urea is very rapidly transformed into carbonate of ammonia, and sewage contains little or no urea, but instead of it the carbonate of ammonia arising from its transformation. In addition to urea, urine contains other nitrogenous matters which are comparatively permanent, and which pass undecomposed into sewage. Now it is a fact which admits of deduction, and which has likewise been confirmed by experiment, that London sewage—such as is discharged by the Fleet Ditch sewer and at Barking—does not contain more organic nitrogen than 0.3 part per 100,000.

No evidence has been laid before the public, or the scientific world, as to the precise numerical limits adopted in the definitions; nor proof that the evil effects of the various impurities specified stand in the exact proportions implied in Section 7. Where is the proof that "organic nitrogen" is safe up to the limit specified, and unsafe beyond? Failing such proof, the recommendations savour of empiricism, wearing the mask of scientific precision.

The use of the terms "organic nitrogen" and "organic carbon" is objectionable, because it implies an official recognition of the process of water-analysis devised by one of the Commissioners, but condemned by the chemical profession as impracticable and fallacious.

The term "organic nitrogen" confounds substances totally distinct in a sanitary point of view. Thus it would include—

- a. Bodies such as *urea*, which is resolved on decomposition into carbonate of ammonia, and which is no more dangerous to health than pre-formed ammoniacal salts, or alkaline nitrates and nitrites.
- b. Bodies like the organic alkaloids, which obstinately resist putrefaction.
- c. Bodies like albumen, gelatin, casein, &c., which rapidly pass into the most offensive phases of decomposition.

To group under one head two bodies so utterly dissimilar in their sanitary bearings as urea and albumen, merely because they both contain nitrogen, is to violate the fundamental laws of scientific classification. Any regulation which ignores such important distinctions must be misleading and dangerous. It is therefore suggested that for the term "organic nitrogen" the more precise term "*albumenoid ammonia*" should be substituted; that is to say, nitrogen present in the form of albumenoid bodies, estimated by the amount of ammonia which they yield.

Similar objections must be taken to the term "organic carbon." It, also, confounds bodies incapable of putrefaction with others exceedingly liable to change, and certain to yield offensive products. Thus, should *alcohol* enter a river, it would neither putrefy nor aid in the multiplication of germs, whilst *starch* would do both. Yet these two bodies would be grouped together as yielding organic carbon.

The third definition would exclude probably all ditches and small brooks, most mountain streams, and many of the most beautiful mountain tarns, for they are frequently sufficiently tinged with peaty extractive matter to succumb to this test. Indeed we are not certain that the water of Bala Lake, from which London was to have been supplied, would always pass this ordeal. Constant disputes would be caused by the impossibility of deciding what was a "distinct colour." One authority would certainly prohibit what another would allow to pass; and if, as we understand is the case, it was the intention of the Rivers' Pollution Commissioners, in drawing up their regulations, to make this clause sufficiently lenient to pass a peaty stream which has the appearance of coffee when viewed in a stratum a foot thick, we can only say that they made a most unfortunate choice of language in which to express their meaning.

Definition 4 is levelled against noxious metals. With the exception of potassium, sodium, calcium, and magnesium on the one hand, and of arsenic on the other, this regulation places all metals on an equal footing. No more stringent rule applies to poisons—such as copper, lead, chromium, &c.—than to aluminium and iron, which are practically harmless. Copper, lead, chromium, &c., should be prohibited as strictly as arsenic. Iron and aluminium occur in many natural springs to a greater extent than these definitions would permit. There is no valid reason why all metals except calcium, magnesium, potassium, and sodium should be excluded if they exceed 2 parts in 100,000. What, for instance, is the objection to strontium? And why should barium, chromium, lead, and copper, all well-known and formidable poisons, be permissible in any

amount below 2 parts in 100,000 of water? There is no special provision against the admission into streams of *phosphoric acid*, which, though innocent in itself, powerfully aids in the promotion of putrefaction and in the multiplication of the lower forms of animal and vegetable life.

Definition 6 certainly requires qualifying. In a clear stream, abounding with fish and water plants, a little chlorine might be an objection. But, considering the filthy state in which most of our large rivers find themselves, we think the endeavour at present should be to induce manufacturers to throw as much chlorine *into* the river as they are willing to waste, and not to fine them unless they keep it out.

The "definitions," whilst laying down rules for the *strength in noxious matter* of any sewage, &c., flowing into a river, totally overlook its *volume* and the ratio it bears to the volume of the river. By this oversight the whole scheme may be entirely stultified, for it is evident that a million gallons of waste liquor thrown into a good sized river may do less harm than a thousand gallons discharged into a small stream.

Again, the act will be easily evaded where it is of most consequence it should be strictly enforced. Take the case of two large manufacturers, A and B, each discharging the same volume and quality of polluting liquid into a river. Let A be situated at the head of a stream, taking the water pure and undefiled as it gushes from the mountain side. Here, if any where, the proposed act should be stringently operative, for any offensive liquid thrown into the river pollutes it throughout its whole course. Accordingly clause 10 of the Act is put into operation, and the offending manufacturer receives written notice from the pollution authority to discontinue the discharge of polluting liquid within twelve months. What will the manufacturer do? He will merely divert a little more of the mountain stream into his works, dilute his waste liquors with the pure water down to the requirements of the law, and snap his fingers at the Act of Parliament. Now it is obvious that such a procedure, though it would literally fulfil the law, would leave the stream as polluted as before, since the total amount of impurities thrown into it would remain undiminished, and would bear the same ratio to the volume of water in the river.

But his fellow transgressor, B, situated 50 miles below on the same stream, will be unable to evade the penalty in this easy manner. His waste liquors, it is true, do not come up to the specified standard of purity; but as the river into which he drains has already passed through three or four large towns, and received the waste liquors of some hundreds of manufactories, it is even less able to conform to the Act. Here the waste liquor discharged by B actually does good rather than harm, inasmuch as it is less impure than the river into which it flows. It is obviously out of B's power to adopt the artifice employed by A, and he accordingly gets fined although his waste liquor is better than the river into which he discharges it, and he cannot therefore dilute it down to the required strength.

Instead of fixing upon a fanciful standard of purity which could never be attained in practice, common sense decides that a waste liquor is fit to be discharged into a running stream if it contain a less percentage of impurity than the water of that stream: the word "impurity" being not strained beyond its

legitimate meaning, or made to include perfectly harmless constituents. A manufacturer at the head of a stream would, it is true, have some difficulty in complying with this requirement, but it would only be fair that one drawing pure water near the source of a river, and then polluting that river throughout its whole course, should be judged by a severer standard than if he were to do exactly the same thing fifty miles below, where the river water, as he received it, was already polluted.

In the case of the highest, one or two works on a river the above rule would fail, and some modification must be introduced; but it would not fail until the natural working of the rule had so far purified the rivers of England as to have carried out, to all intents and purposes, the objects of the proposed Act.

Another great advantage of some such elastic, self-regulating rule as the one sketched out above would be that its action would be gradual. The purification of a river would take place by imperceptible gradations, extending over perhaps a year or two, without pressing hardly on any one. In this way time would be allowed manufacturers for making arrangements

to purify their waste liquids; and as the river gradually increased in purity by the natural working of these regulations, we have little doubt that the progress of science, and their own increased experience, would enable manufacturers in almost all cases to keep their effluent liquids up to the necessary standard.

COMPARISON OF BUTTER WITH OTHER FATS.

By J. CAMPBELL BROWN, D.Sc.

THE proportions of the chemical constituents vary so greatly (from zero upwards) that no reliable evidence of purity or impurity can be obtained by estimating the different fats obtainable by decomposing butter. In fact, the distinction between pure butter and butter mixed with flesh-fats is no more a chemical one than the distinction between different animals or different plants. The physiologist distinguishes one kind of tissue from another more readily by their microscopic characters than by their chemical composition; and microscopic examination with polarised light is the most reliable means of distinguishing pure butter from that which contains an admixture of less easily digestible and less palatable fats.

No.	Designation.	When Heated		On Cooling			Solid at Fahr.	Examined by a Microscope with 4-inch Object-Glass with Polarised Light and Selenite Plate.	Deposit from 3 ozs. Ether at 65°.		Fuses at Fahr.	Solidified at Fahr.
		Softens at Fahr.	Melts at Fahr.	Obscures reading.	Stem indistinct.	Stem invisible.			Curd and Salt in grs. per oz.	Weight in grs. per oz.		
10.	Newly-made butter, from town-fed cows	69	76	83	76	73	62	{ Nothing is seen except globules and curd.	—	2.6	137	118
	The same salted ..	69	75	83	75	74	62	{ Globules, particles of curd; cubical crystals of salt.	32.5	—	—	—
8.	Irish butter	75	89	73	71	69	62	{ Globules, curd and salt; does not polarise. After being kept for nine months does not exhibit any crystals which polarise light.	—	1.7	133	114
4.	Irish butter, best quality	69	80	78	74	71	66	{ Globules, curd and salt. After being kept for eight months, exposed to sun, is white, but contains no crystals which polarise light; nor after being melted.	30.8	3.0	134	115

A NEW THEORY OF THE FIELD OF VIEW AND MAGNIFICATION OF OPTICAL INSTRUMENTS.

IN a recent number of *Poggendorff's Annalen*, Prof. Lubimoff, of Moscow, calls attention to an error which has long passed current in text-books on physics. It is generally said that the field of view of the Galilean telescope is dependent on the size of pupil of the observer's eye, and is measured by the angle subtended by the pupil's aperture from the middle of the objective. In this way it is represented as being five or six times less than it actually is. He quotes from various text-books, those of Wüllner, Pouillet, Müller, Reis, Daguin, Potter, and others, in illustration of his statement.

The error he traces to Euler, who wrongly applied to the case of a concave eye-piece, a principle which holds good in the Keplerian telescope. The central rays diverge from the centre of the object-glass, as from one point, and are united in a point where the eye-piece, if a convex lens, gives an image of the aperture of the objective. If the eye is in this position, it receives all central rays which fall on the eye-piece; hence the latter operates with its whole aperture. As, with a concave eye-piece, the central rays diverge, the eye, when applied to it, receives only so many rays as pass through the aperture of the pupil. This remark, the Professor points out, is quite correct with reference to central rays, but does not warrant a conclusion as to the field of view, for a considerable portion of the image on the retina is formed without central rays, and only by the side parts of the object-glass.

We propose to follow the author in the elucidation of his views on this subject.

To understand the true theory of the phenomenon, it may be well to resort to a principle which is often of use in explaining the elementary theory of images. This is, that we regard the image-forming apparatus (lens or mirror) as an aperture or a window, and the image itself as an object placed behind the aperture, and looked at through it. Apply this principle to the Galilean telescope. When we look through the telescope we see a bright circle before us, in which several objects appear, and which plays the part of the supposed window. What is this circle? It is easy to understand that it is no other than the subjective image of the object-glass aperture, produced through the dispersive eye-piece. (The size of the diaphragm may here be regarded as identical with that of the subjective image.) As, now, from the middle point of a lens, every object is seen under about the same angle as its image, we may take as approximate measure of the angular size of the diameter of the bright window (the eye being at the optical middle point of the eye-piece), the quotient obtained by dividing the diameter of the objective from the eye-piece, say $\frac{D}{\Delta}$;

being, according to the theory of the telescope, equal to the difference, $F_1 - F_2$, the focal distances of objective and eye-piece. Expressed in angular measure, the quotient will be—

$$\frac{360}{2\pi} \cdot \frac{D}{F_1 - F_2}$$

If we looked at the object through a window of the same angular size as the bright circle with the naked eye, this number of degrees would directly express what is the greatest part of the entire circle of external objects we can see at once. To determine this practically it might be well to remove objective and eye-piece, and, without altering the position of the eye, look through the empty tube. Now, as the telescope magnifies n times, i.e., brings the object, so to speak, n times nearer to the eye, we shall, with the telescope, view through an aperture of the same visible size as formerly, an n times smaller part of the external circle of objects. To find the true field of view of a Galilean telescope, therefore, the above ex-

pression must be divided by n , or by $\frac{F_1}{F_2}$; as, according to telescope theory, n is about equal to this proportion. Hence the field of view is—

$$\frac{360}{2\pi} \cdot \frac{D}{F_1 - F_2} \cdot \frac{F_2}{F_1}$$

The relation shown to exist between field of view and magnification affords a ready method of estimating the latter. One has only to look with the naked eye through an aperture, whose visible size is equal to that of the bright circle, and to compare the included space with that seen through the telescope (e.g. to count how many windows in a building, seen through an aperture, and seen through a telescope).

The theory asserts that the field of view of a Galilean telescope is immediately dependent on the size of aperture of the objective.

It can be shown what part of the objective shares in the production of a given part of an image, and the following mode of doing so gives a new point of view as to

FIG. 1.

FIG. 2.

the theory of the telescope. Let $M M'$ (Fig. 1) be the objective, $P P$ its focal plane, in which distant objects are imaged. Bring between the objective and the plane a diaphragm with small opening. The image will be formed as before; only that each point of the image is no longer produced through the union of all the rays of a conical bundle, having the whole objective as its base; but only by that part of the bundle which passes through the small opening, and may be regarded as a single ray. Thus, for a given point of the image, only that small part of the objective will send rays which correspond to the straight line going from said point through the opening to the objective. The limits of the image will be determined by the lines $M A$ and $M B$. Now, substitute for the diaphragm a Galilean eye-piece, behind which is the observer's eye. The phenomenon is in its main features the same; for we may regard the eye as a dark chamber, on whose further wall (the retina) the image is formed. The optical part of the eye and the eye-piece merely serve to make the retinal image distinct, and may, for theoretical treatment, be replaced by a lens fixed in the widened part of the diaphragm ($m m$, Fig. 2). The difference between the action of such a lens and that of

the small opening lies in this, that the image is distinct in the former case only when the screen stands at a particular distance, and that nearer to the lens than its focal plane, *P P*, e.g. at *a b*. And the same angle will correspond to both images. That part of the objective which shares in the production of a given image-point, will be determined by the lines drawn from said point to the edges, *m m*, of the lens, and prolonged thence to the objective. Corresponding to the contour of the supposed lens, we must evidently take the pupil aperture of the observer's eye. Let *E* be the diameter of the pupil, *x* that of the operative part, *p p*, in the objective, the size of this latter will be determined approximately by the equation—

$$\frac{x}{F_1} = \frac{E}{F_2}$$

The foregoing contains the entire theory of the Galilean telescope. The retina is the flame which receives the image, *a b*. As this image is inverted, like all retinal images, we see the objects upright. The visual angle, under which the part of the visible circle imaged in *a b* appears, is determined by the lines drawn from the middle point of the lens, *m m*, to *a* and *b*, or (the same thing) to *A* and *B*, and is measured by $\frac{AB}{F_2}$. The visual angle under which the same portion of visible space would appear to the naked eye, supposing this to be at the middle point of the objective, will be determined by the lines drawn from this middle point to *A* and *B*, and measured by $\frac{AB}{F_2}$. The proportion of these two angles is the magnification—

$$n = \frac{F_1}{F_2}$$

As through the telescope we only see, at once, that part of the outer circle whose image in the focal plane of the objective extends over *AB*, the expression—

$$\frac{360^\circ}{2\pi} \cdot \frac{AB}{F_1}$$

gives us directly the value of the field of view. But—

$$\frac{AB}{D} = \frac{F_2}{F_1 - F_2}$$

where *D* denotes the diameter of the objective, and $F_1 - F_2$ the distance between it and the point at which are eye and eye-piece. Thus we obtain the expression formerly given for the field of view:—

$$\frac{360^\circ}{2\pi} \cdot \frac{D}{F_1 - F_2} \cdot \frac{F_2}{F_1}$$

Finally, we may find the value of the field of view immediately, as follows:—Suppose, instead of the objective, a simple aperture, *m m* (Fig. 3). Then the eye, being at *o*,

FIG. 3.

would perceive the portion of space which corresponds to the angle *s o s*, and the rays *m o m* would come from the outermost visible objects, lying in the directions *s o s*. In consequence of refraction in the objective the rays, *m o m*, proceeding to the eyes, do not form a straight prolongation of the rays, *s' m s'*, which meet, not in *o*, but further on, at *o'*, at the distance *x* from the objective.

Consequently, the limits of visible space are determined by the angle *m o' m*. The side of the field of view will be equal to—

$$\frac{D}{x} \cdot \frac{360^\circ}{2\pi}$$

The distance, *x*, is obtained by the formula for conjugate foci; as *o* and *o'* are conjugate foci, then—

$$\frac{1}{F_1 - F_2} - \frac{1}{x} = \frac{1}{F_1}$$

Hence the field of view is, as before,—

$$\frac{360^\circ}{2\pi} \cdot \frac{D}{F_1 - F_2} \cdot \frac{F_2}{F_1}$$

Prof. Lubimoff further shows how the same theory applies to the Keplerian telescope.

He next discusses some optical illusions, which permit of being explained by his theory of optical windows.

It is known that a convex lens magnifies objects placed behind it at a distance smaller than the focal distance. It has probably been observed by many that when, with distance of lens from object unchanged, we move away from the lens, the object seems to grow larger, especially if it is in the neighbourhood of the focus, and, e.g., consists of a series of dark lines on a white ground, as lines in a book. Judging from first impressions, it is difficult to believe that this obvious increase of the object is an illusion, and that, in reality, the size of the image on the retina—or, in other words, the angle under which the object seen through the lens appears to us—is diminished when we move away. This is indeed the case, however; the magnification is only apparent. An experiment like the following is fitted to show this. Behind the lens, *a a* (Fig. 4), at a distance shorter than its focal, stands a pasteboard screen, *m n p q*, on which a number of parallel equidistant lines are drawn. Behind this screen is a second and larger one, *M N P Q*, placed at the distance at which, according to the theory, that portion of the smaller screen seen through the lens appears to be. It is further understood that the lines drawn on the larger screen stand as far apart as, apparently, do the lines of the first screen seen through the lens. In this case that part of the screen (*m n p q*) which is visible through the lens will have the same appearance as the directly seen borders of the screen, *M N P Q*; and if one of the lines seen through the lens coincides with one of the lines on the larger screen, all the other lines seen through the lens will also correspond with lines on the larger screen. Now it appears, from experiment, that on moving away from the lens this coincidence continues. At the same time we observe that the number of lines visible through the lens is diminished.

The cause of the apparent enlargement referred to (on withdrawing from the lens) lies in the fact that while in

FIG. 4.

one position, perhaps, 14 lines are visible; if the eye is further removed, only 8, 5, &c., lines are visible in the same field of view. Without reckoning for the distance of the eye from the screen, the observer arbitrarily infers—from the different number of lines in the field of view—that their distance from each other is altered, this distance appearing greater where few lines are visible.

A curious observation may be made in the act of reading. When we look through an opening at the lines in a book, placed not far behind the opening, and when we move away from it, the letters appear at first (and so long as we can read) clearly diminished; when, however, light has become indistinct, and we can no longer read, the lines and their distance from each other appear to increase, just like the lines on the screen in the former case. So long as we are able to read distinctly, we pronounce judgment on the distance of the book and the size of the letters, according to the greater or less difficulty we have in reading; beyond this, however, we draw the same inference as in the case of the screen.

CORRESPONDENCE.

ON BUTTER.

To the Editor of the Chemical News.

SIR,—The conclusion which I drew when I read through Dr. Campbell Brown's paper "On Butter," viz., that the author of it appeared "not to know that butter resembles suet, tallow, dripping, and lard, by containing, as they do, stearin, olein, and palmitin, and that it differs from them only by containing very small quantities of butyric, &c.," has doubtless seemed rather harsh to some of your readers. Dr. Brown's letter, however, confirms my construction of his paper. As there seem to be persons who call for a detailed criticism in this instance, and who, with Mr. Catcheside, appear to require a more explicit statement, I will enter into particulars.

Touching *stearin*. This fat is well known to chemists to be of very frequent occurrence. In butter it was found by Chevreul long ago, and more recently by Heintz; and its existence in butter is generally admitted by chemists, as may be seen on looking into chemical text-books or into "Watts's Dictionary."

Now in Dr. Campbell Brown's paper (*vide* CHEMICAL NEWS, vol. xxviii., p. 1) butter is defined as follows:—"Chemically it consists of a mixture of neutral fats, the glycerides of the non-volatile acids, palmitic acid ($C_{16}H_{32}O_2$), and butyric acid ($C_4H_8O_2$); and the glycerides of the volatile acids, butyric acid ($C_4H_8O_2$), capronic acid ($C_6H_{12}O_2$), caprylic acid ($C_8H_{16}O_2$), and capric acid ($C_{10}H_{20}O_2$).—(Wagner and Crookes). The last four glycerides are the characteristic fats of butter." Thus Dr. Brown enumerates six glycerides as constituents of butter, but omits to mention stearin, the glyceride of stearic acid. It will probably be suggested by charitable chemists that all which follows from this circumstance is that Dr. Brown forgot to put stearin on the list. A further examination of the paper led me to reject this hypothesis; and Dr. Brown's letter will, I think, be admitted—even by Mr. Catcheside—to have excluded any such explanation.

Dr. Brown now writes that "stearin can sometimes be obtained from butter and sometimes not; but it does not occur in butter as crystallised stearin."

I do not think I need make any further comment on this statement. Touching olein, this compound, which is the glyceride of oleic acid, is mentioned by Dr. Brown as existing in certain fats, such as beef suet, &c., but is not mentioned among the constituents of butter. Instead of it, the glyceride of what Dr. Brown calls butyric acid—an acid to which the formula ($C_{12}H_{24}O_2$) is assigned—takes its place. Some chemists may suggest that the name is an eccentricity, and the formula a misprint; but in his letter Dr. B. does not correct the formula.

With regard to palmitin, Dr. B. says in his paper that palmitin is one of the most characteristic ingredients of suet, &c., and leaves us in doubt whether or not he believes it to exist in butter; the glyceride which he attributes to butter being the glyceride of palmitic acid (instead

of palmitic acid). A tolerably correct knowledge of the constitution of butter is an indispensable preliminary to the detection of the adulterations of butter. With the hint that there is nothing improbable in the separation of impure stearin from butter placed under certain obvious physical conditions, I will therefore close my letter.—I am, &c.,

J. ALFRED WANKLYN.

London, July 19, 1873.

ON BUTTER.

To the Editor of the Chemical News.

SIR,—In estimating the water in butter, the presence of dripping can also be detected at the same time, by the peculiar odour of roast meat, and any one with a keen sense of smell can say whether beef or mutton dripping is the adulterant.

In the elaborate and interesting analysis of butter which Dr. Brown has given us, there is work enough for at least two days, particularly as a pure sample of butter has to be analysed along with it. May I ask, is it necessary for every Public Analyst to make such a minute examination? Surely the presence of dripping, starch, or any foreign matter, is quite sufficient to produce a conviction, without being obliged to state the quantities; and the low fees which are paid for these analyses utterly preclude such elaborate examinations. For instance, Dr. Cameron has just been appointed Analyst to the County of Sligo, with the liberal salary of £25 a year, and weighted with this addition—that the charges for analysis are to range from 2s. 6d. to 10s.; and as Ireland is a great butter-producing country he will find his place no sinecure,—that is if he follows strictly the examination given by Dr. Brown.—I am, &c.,

J. CARTER BELL.

The Manchester Laboratory,
18, Exchange Street, July 21, 1873.

ON BUTTER.

To the Editor of the Chemical News.

SIR,—A little relaxation on Saturday last enabled me to become acquainted with the abstract of Dr. Campbell Brown's paper on the "Analysis of Butter" (CHEMICAL NEWS, vol. xxviii., p. 1), and the correspondence it has occasioned.

I have heard a good deal from the Doctor already about his method of analysing butter, in relation to a local inquiry. The published abstract is much more consecutive in details than the Doctor's replies to questions in the witness box. From the latter it would be inferred that he considers stearin and palmitin to exist in butter in a state analogous, if not identical, with that of carbon in sugar or paraffin; also that butter is physically constituted of an aggregation of globules in a manner similar to that of starch, German yeast, and such like bodies. This statement is repeated in the abstract of Dr. Brown's paper, section 3. It is such a novel assertion on the part of a scientific man, that I do not wonder Mr. Wanklyn's patience was a little ruffled by the study of it.

Respect for real or reputed scientific attainments, such as those accorded to Dr. Brown, determines me to give the statement that commercial butter, fresh or salt, is mainly composed of globular matter some consideration. I might, indeed, affirm a direct negative, as I did elsewhere, and so save time and space; but it may be well to add my reasons for the benefit of some readers who possibly may not be conversant with the subject.

Firstly, then, the matter of butter as it exists in fresh or new milk, presents the form of minute liquid globules. The microscope reveals that the globular form of the fat matter is due to the repulsive action of the aqueous menstruum and the liquid fat, and not to any enveloping tissue or coating which would conduce to the retention of the globules in their entity. When lactic acid is de-

veloped in the milk in sufficient quantity to overcome its natural alkaline condition and the milk is then churned, the diffused globules are made to adhere, and the result is a mass of solid butter of greater or less hardness, according to certain physiological conditions of the animal and its food. Now as the fat globules as observed in milk are devoid of cell walls, or envelopes, other than the aqueous medium in which they are diffused, it will be readily understood that when any number of them is made to adhere by the mechanical action of churning, the globular form presented in the milk will disappear, and other considerations being for the moment set aside, the resulting butter will present a homogeneous non-globular appearance under the microscope. Butter really does present this non-globular aspect when so examined.

Butter is not exceptional in this respect. All fatty substances, whether liquid or solid when educed as fats, from the bodies secreting them, animal or vegetable, are non-globular in their structure.

It is well to note the physical change impressed on the fat of milk by churning. Before this operation the globules in the milk are transparent and liquid; after, the fat is solid. Without going deeper into the consideration of the principle evolved in this change, I think it will be accepted as the result of the crystallisation of such constituents of the fat as are capable of assuming this state. Stearin and palmitin are such constituents. The crystals of the latter constituents are, however, so small in freshly churned butter as not to be defined by a $\frac{1}{4}$ -inch power; but let the butter when churned be washed with tepid water of 75° to 80° F., or let it be exposed after washing to a summer heat and then cooled, the crystals then become so large as to be readily discerned even by lower powers than a $\frac{1}{4}$ -inch objective. This fact is singularly confirmed in Dr. Brown's paper; and also the assertion that stearin and palmitin are not present as such in butter, as forcibly controverted. He states correctly that butter becomes opaque under 74° F.; above this heat a transparent fluid. Here the opacity is due to the separation of crystalline matter, and that matter stearin and palmitin, in varying proportions. If these constituents of butter existed in it as carbon exists in sugar or paraffin it would not be conceivable how the separation could so easily be effected. Dr. Brown, however, recently determined that certain butters submitted to him were adulterated, because he found crystallised matter in them; and corroborated his conclusion by the assertion that stearin, palmitin, and olein were not proximate components of butter. I use these names as synonyms of Dr. Brown's *glycerides*, and I dare say Mr. Wanklyn so comprehends them.

Regarding the estimation of water in butter, which varies from 8 to 20 per cent, a temperature of 212° in either water or air bath as prescribed by Dr. Brown, is inadequate. An approximate result may be obtained if the heating process were continued for a greatly disproportionate period, say a week, but not in the time devoted by analysts to such work.

Looking at Dr. Brown's paper as the exponent of his course of procedure, I may ask whether it is possible for him to execute the operations stated therein for the sum of 7s. 6d. and 5s. of current coin? for these it appears are the highest fees which he can charge in his official capacity.

Chemists appointed to carry out the provisions of the Adulteration Act, are introduced into a wide field of chemical study,—one which demands enlarged knowledge and experience to explore it, but from which much practical and valuable information can be obtained. Crude inconsiderate processes in the execution of the work will not add much lustre to the scientific standing of the analysts; and it may be well to show at the outset that conclusions founded on such crude or unreliable operations will not be accepted from them.—I am, &c.,

MARTIN MURPHY, F.C.S.

College of Chemistry, Liverpool,
July 21, 1873.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Under this heading will be found an encyclopaedic list of chemical papers published abroad during the past week, with abstracts of all susceptible of advantageous abridgment. The two half-yearly volumes of the CHEMICAL NEWS, with their copious indices, will, therefore, be equivalent to an English edition of the "Jahresberichte."

NOTE. All degrees of temperature are Centigrade, unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances de l'Académie des Sciences, June 30, 1873.

Reflections on a Memoir of La Grange, entitled "Essay on the Problem of Three Bodies."—M. Serret.

Extract from Memoir on the Analytical Theory of the Satellites of Jupiter.—M. Souillat.

Researches on the Reflection of Solar Heat at the Surface of Lake Lemman.—M. Dufour.—The author experimented at five stations between Lausanne and Vevey, using three blackened bulbs containing thermometers. The first, suitably screened, gave the temperature of the air; the second, screened against direct solar radiation, received reflected heat; the third, unscreened, received both direct and reflected heat. The greatest proportion of reflected heat was 0.68 of the incident heat, and this was obtained with solar heights of $4^{\circ} 38'$ and $3^{\circ} 34'$. About 7° , the proportion was 0.4 or 0.5; about 16° , it was 0.2 or 0.3; while, if the sun was higher than 30° , the reflection was hardly appreciable. The author, however, failed to establish a law between the proportion of reflected heat and height of the sun. At stations some distance from the lake the proportion of heat reflected did not seem to increase with greater nearness of the sun to the horizon; the absorption by air probably compensating the increase which would otherwise appear. Most heat is reflected when the lake is calm. While a greater proportion of heat is reflected as the sun nears the horizon, the intensity of the direct ray diminishes, so that we come to a maximum of actual quantity of heat reflected. This maximum varies with the state of the surface and the diathermancy of the air. The total heat reflected, from the time at which reflection became sensible till sunset, was, at one station, in September, about equal to the heat radiated directly by the sun during the last three quarters of an hour before setting; at another station, in October, equal to that radiated directly in the last half-hour, &c. (various such comparisons were made). It was also approximately ascertained what absolute quantity was reflected by the lake in a square metre of a surface normal to the ray; this was, at four several stations, 104, 84, 112, and 134 calories respectively, in September and October. The foregoing results doubtless apply also to the sea, and have an important bearing on climate, vegetation, &c.

New Observations Proving the Presence of Magnesium in the Entire Border of the Sun.—M. Tacchini.—These observations were made on the 21st to the 23rd of May last. The author states it is clearly proved that there is greater activity in the northern hemisphere of the sun than in the southern, and that the general presence of magnesium corresponds to a minimum in the number of protuberances.

Note on Magnetism.—M. Gauguain.—The author indicates the mode in which he obtains the curves of demagnetisation, where an armature of soft iron is applied to the polar faces of a horse-shoe magnet, and withdrawn. It depends on the currents of induction produced in a wire. He thinks the idea of a condensation of magnetism near the surface of contact an erroneous one; for, when the armature is applied as stated, the magnetisation caused by currents of induction increases throughout the

extent of the horse-shoe, to the heel, or middle of the curve. Some other observations, with armatures of various shape and size, confirmed this. Again, when a soft iron bar is applied perpendicularly to the (length) surface of a horse-shoe magnet, the magnetic intensity appears to diminish about the bar, and it is commonly said that the magnetism, attracted by the soft iron, is condensed at the surface of contact. The author questions this; for if, before applying the bar, the curve of demagnetisation of the branches of the horse-shoe be determined, and then the changes this curve undergoes after application, it is found that the curve is divided in two; the part between the bar and the extremity of the branch falls, and that between the bar and the middle of the curve rises, *i.e.*, the magnetisation diminishes on one side and increases on the other. How, then, will the condensation of magnetism explain the increase in the one region? It is easy to understand, on the other hand, how the opposite modifications of the curve of demagnetisation result in a diminution of magnetic intensity; which intensity depends on the inclination of this curve, and this diminishes, at the same time, for both parts of the curve. The author further compares his method of determining the intensities at different points of a magnetised bar with the method of oscillations adopted by Coulomb. The curves agree, except near the extremity of the bar, where, therefore, a simple relation M. Gauguain had established between the magnetic intensity and that of the solenoidal current no longer exists.

Cooling and Freezing of Alcoholic Liquids and Wines.—M. Melsens.

Calculation of the Moments of Inertia of Molecules. M. Hinrichs.

Note on the State of Sericulture in 1873.—M. Guerin-Meneville.

Comparison of the Indices of Refraction in Certain Isomeric Compound Ethers.—I. Pierre and E. Puchot.—The authors conclude that the numerical magnitude of the Index of Refraction, at least in the compound ethers, depends more on the chemical equivalent of the body than on its specific gravity.

Decomposition of Metallic Carbonates by Heat.—M. L. Joulin.—The carbonate of manganese was appreciably decomposed at 70°. Up to 200° this decomposition presents the characters of the phenomenon which Deville has named *dissociation*, *i.e.*, at a given temperature the tension of the carbonic acid, after a longer or shorter time, attains a value which remains constant, and that during the time of cooling the tension gradually returns to its primitive value, in consequence of the recombination of the carbonic acid and of the protoxide of manganese. From 250° to 300° the elastic force of the carbonic acid constantly increases up to two atmospheres. The body, which up to 200° had remained whitish, grows brown, the protoxide of manganese decomposing part of the carbonic acid, in order to convert itself into sesquioxide. Prolonged heating seems to render the carbonates more stable.

Production of Glycerin from Propylen.—C. Friedel and R. D. Silva.—The authors furnish confirmations of their former experiments and conclusions (*Comptes Rendus*, vol. lxxiii., p. 1379) to meet certain objections urged by Berthelot.

On a Glycerin of the Aromatic Series.—M. E. Grimaux.—The author endeavoured to obtain $C_9H_{12}O_3$; in other words, a molecule of glycerin in which an atom of hydrogen is replaced by the phenylic group, C_6H_5 .

Determination of Sugars by Barreswill's Method.—M. Loiseau.—Feltz has shown that when the cupro-tartaric liquid is alkaline, the soda reacts upon crystallisable sugar. The author had previously recommended various chemists to dilute with water the cupro-potassic liquids used for determining the small quantities of non-crystalline sugar which occur in the produce of the Paris

refineries. The author has since proved the existence of another source of error which soda may cause in the determination of glucose by Barreswill's method. This is due to the fact that soda promotes the restoration of a blue colour in the cupro-potassic liquid which has been decolourised under the influence of a sufficient quantity of non-crystalline sugar. Thus an excess of soda gives results below the truth. The test-liquor employed was prepared according to the formula of Fehling. It is needful to ascertain what proportion of soda should be present in the test-solution. This proportion can neither be increased nor lessened at random, since, if an excess of soda favours the re-colouration of the liquors, a too feeble alkalinity protracts too much the decolouration of the liquid. It appears that Barreswill's method employed for the determination of glucose may yield different results, according to the manner in which it is used. The alkalinity of the liquid should be such that a litre may be neutralised by 240 c.c. of decinormal sulphuric acid. With this precaution the method gives results accurate enough for all commercial purposes. It may even be applied to the determination of raw sugars, and may furnish results as accurate as those given by polarimetric assays. On a future occasion the author will give what he considers the best formula for the test-solution, and explain why it should be protected from the carbonic acid of the atmosphere.

Erythrophenic Acid, a New Reaction of Phenol and Anilin.—E. Jacquemin.—We have given a summary of this paper elsewhere.

On Crystalline Protiodide of Mercury.—P. Yvon.—This compound is best obtained by heating mercury and iodine in equivalent proportions, in sealed flasks, upon the sand-bath. The temperature must not be allowed to exceed 250°. The upper portion of the flask will be found lined with crystals of a fine red, which become yellow on cooling. On re-heating, the red colour begins to return at 70°, and at 220° a splendid garnet shade is attained. This is exactly the inverse of the phenomena presented, under similar circumstances, by the biniodide. The crystals of protiodide melt at 290° to a black liquid, which boils at 310°. If more rapidly heated it is decomposed, yielding mercury and a light yellow sublimate, which is not, as might be expected, a compound richer in iodine, but an oxy-iodide which may be represented by the formula $Hg_{13}O_6I_7 = 6HgO, 7HgI$. This oxy-iodide is at first bright yellow and crystalline, but, especially if exposed to the light, it soon becomes first orange and then brick red, and falls to a powder.

Bulletin de la Société Chimique de Paris, tome xx., No. 2, July 20, 1873.

Determination of Ferric Oxide by Means of Hyposulphite of Soda.—J. M. Crafts.—The most convenient solvent for ferric oxide in iron ores is commonly concentrated hydrochloric acid, but such solutions are not well adapted for titration with permanganate of potash. They are, however, perfectly adapted for volumetric determination with hyposulphite of soda. This method, performed as has been hitherto recommended, is not as exact as could be desired. The author has endeavoured to eliminate the causes of error in this procedure, which is recommended by its rapidity of execution and by the stability and easy preparation of the reagents employed. The only cause of error lies in the decomposing action which the free acid of the ferric solution exerts upon the hyposulphite of soda, and care must be taken to diminish this excess of acid to the point where its disturbing action becomes inappreciable. The following procedure renders it possible to obtain results as exact as can be expected from a volumetric method. The following solutions are needed:—*Hyposulphite of Soda*.—The commercial salt, purified, should be well dried at common temperatures. It is exposed for several days in

thin layers between folds of blotting-paper, and is pulverised afresh every day to expose to the air fresh surfaces. It is only after the lapse of several days that a product is obtained sufficiently dry and well powdered. The salt, thus prepared, no longer loses weight in dry air, and after its value has been determined, a normal solution may always be obtained by dissolving in water the weight indicated by experiment. If the salt is pure, the amount necessary to dissolve in water to obtain a viginti-normal solution is 12.4 grms. Such a solution keeps its value for a month, within 0.2 or 0.3 per cent. The solution of perchloride of iron which serves as standard for these experiments is made by dissolving pure iron, whose percentage of carbon is known, in strong hydrochloric acid. A few drops of nitric acid are added; the mixture is boiled for a few minutes, and then evaporated, till the crust of ferric chloride which forms begins to re-dissolve with difficulty in the acid solution. During the ten minutes which the latter part of the evaporation requires, it is necessary to watch attentively, so as not to pass the proper point. To make a viginti-normal solution of iron, it is necessary to dissolve in a litre of water 2.8098 grms. of fine iron wire, containing 99.65 per cent. of metallic iron. It is of importance that solutions more concentrated than viginti-normal should not be used. The analysis may be made by adding the hyposulphite in known excess, and titrating back with iodine to ascertain the surplus of hyposulphite. As nearly as possible, the same excess of hyposulphite should be used on each occasion. The reduction is completed in five or six minutes, and its termination is ascertained by adding a little sulphocyanide of potassium, which should not give a red colouration. The well-known reaction between iodine and starch, which indicates when a sufficiency of iodine has been added, is not appreciably diminished in sensibility by the volume of the liquid. In practice, an iron ore is boiled in hydrochloric acid in order completely to dissolve the ferric oxide, and the solution is evaporated down to the point indicated above. If the protoxide in an ore is also to be determined, the evaporation must be preceded by oxidation. It is convenient to take for each analysis 1.4 gr. dissolved in half-a-litre. A preliminary titration serves to determine approximately the quantity of hyposulphite equivalent to 100 c.c. of the ferric solution, and in the final operation 20 per cent more hyposulphite is taken. Water which is added during the analysis must be deprived of atmospheric oxygen by boiling. Ferric chloride reduced to the ferrous state during an analysis of the procedure indicated may be exposed to the air for twenty-four hours without becoming sensibly oxidised.

Heat Liberated in the Reaction between Water, Ammonia, and the Alkaline Earths, Lime, Baryta, and Strontia; Constitution of Alkaline Solutions.—M. Berthelot.—A lengthy thermo-chemical paper.

On Certain Ammoniacal Salts of Silver.—M. O. Widman.—The salts in question have been obtained by dissolving the salts of silver in an excess of ammonia, and crystallising over a mixture of quick-lime and sal-ammoniac. The original silver salts were obtained by precipitating nitrate of silver with alkaline tungstates, molybdates, and arseniates.

On Certain Compounds of Zirconium.—S. R. Pajkull.—The compounds examined are the chloride, phospho-chloride, tetrachloride, sulphide, oxychloride, hydrate, sulphate, arseniate, and orthophosphate.

Action of Chloride of Benzyl upon Naphthylamin.—Ch. Frôté and D. Tommasi.

Erythrophenic Acid, a New Reaction of Phenol and Aniline.—E. Jacquemin.—When phenol is treated with chlorine-water, no reaction is observed, and ammonia added to the mixture subsequently develops no colouration. It is known that aniline, on the contrary,

suspended in water, with the addition of a solution of chlorine, takes a rose colour, which rapidly becomes purple, violet, and, lastly, brownish red, and that ammonia added at this last juncture increases the brownness. It is no longer the same when a mixture of a drop of phenol and a drop of aniline is submitted to the action of solution of chlorine. A permanent rose-red is obtained, which may be turned to a blue either by ammonia or by the alkalis or alkaline carbonates. Acids restore the original redness. The author concludes that there exists a phenate of phenylamin; that the new body produced in the above reaction is a red acid, forming blue salts; the erythrophenate of soda may be produced by causing hypochlorite of soda to act upon the mixture of phenol and aniline. The blue thus formed is remarkable for its purity and extraordinary tinctorial power. If two drops of the mixture of phenol and aniline be added to 2 litres of water, and then treated with hypochlorite, the blue in an hour or two becomes so intense that it could be recognised even in 4 litres of water. This reaction may be useful in toxicological researches either for aniline or phenol. The purity and permanence of the blue might render it fit for the uses of the dyer, but it will not bear steaming. The extreme facility with which it is reddened by the feeblest acids is likewise an objection. In this respect it far exceeds litmus.

Transformation of Succinic Acid into Maleic Acid.—E. Bourgoin.

Ethylacetylen Formed Synthetically, and on its Identity with Crotonylen.—L. Prunier.—The identity of those two substances has been established by a comparison of their tetrabromides.

New Method of Producing Chlorine.—F. de Lalande and M. Prud'homme.—Lamy, in examining the action of a mixture of hydrochloric acid and of air upon silicates or mixtures of silica and chlorides, which the authors had previously studied, seems to ascribe the evolution to the presence of oxide of iron in the substances brought in contact. It must be observed that the reaction may be thus expressed: oxygen displaces chlorine from chlorides at a red heat, and in presence of an acid capable of uniting with the base thus formed. A mixture of hydrochloric acid and of air may thus give rise to a continuous evolution of chlorine. The authors have experimented in glazed earthen tubes upon 10 grms. of fused chloride of sodium and 10 grms. of fused boracic acid placed either separately or together in a porcelain boat, and have found:—That chloride of sodium and boracic acid taken singly give at redness, in a current of dry air, mere traces of chlorine. In the same conditions a mixture of the two enabled us to collect 15 per cent of the chlorine present in the chloride of sodium. The displacement of chlorine by oxygen has been obtained in presence of the silicic, boracic, phosphoric, and stannic acids, and of alumina. The influence of the oxide of iron or other impurities is insignificant.

Composition of Bone Phosphate.—C. Aebé (*Journal f. Praktische Chemie*, vol. vi., p. 169, 1872).—For each equivalent of tricalcic phosphate the author finds half an equivalent of crystallised water; one-third of basic water, not expelled below 450°; one-third equivalent of lime in excess; and one-sixth equivalent of carbonic acid. The composition of bone earth is therefore highly complex.

Chemical and Crystallographic Notes on Certain Salts of Glucinum and the Cerite Metals.—C. Magnac (*Archives des Sciences de la Bibliothèque Universelle*, March, 1873).—The author examines the fluoride of glucinum and potassium; fluoride of glucinum and sodium; fluoride of glucinum and ammonium; sulphate of cerium; nitrate of lanthanum; nitrate of didymium; nitrate of cerium; ammoniaco-nitrate of lanthanum; ammoniaco-nitrate of didymium, and the chloro-platinates of the group. The author concludes the atomic weight of lanthanum to be 92.5.

Analysis of a Fossil Human Bone.—M. Terreil.—In one portion the carbonate of lime was 64.33 per cent, whilst the phosphate amounted merely to 17.12.

Influence of the Different Colours of the Spectrum upon the Decomposition of Carbonic Acid of Plants.—W. Pfeffer (*Pog. Ann.*, vol. cxlviii., p. 86, 1873, No. 1).—Taking the amount decomposed under the yellow ray at 100, the following scale was obtained:—

Red..	25.4
Orange ..	63.0
Yellow ..	100.0
Green ..	37.2
Blue ..	22.1
Indigo ..	13.5
Violet ..	7.1

Reimann's Färber Zeitung, No. 26, 1873.

Dialysed Iron.—For mordanting silk, &c., iron can be applied in the state of dialysed oxide. To prepare this compound, a solution of iron oxide in hydrochloric acid is introduced into the dialyser. After some time, the hydrochloric acid will be found to have escaped into the surrounding water, whilst the oxide of iron remains in the dialyser in a soluble condition, free from any hurtful amount of acid. This solution is found remarkably well adapted for dyeing heavy blacks upon silks, which it mordants in perfection without "tendering" the fibre. It would seem as if every case of mordanting was a dialytic phenomenon, the fibre being in effect a conglomerate of membranes. The degree to which the iron solution is to be deprived of its acid is a matter to be determined by experience in such class of cases.

Practical Receipts.—The editor gives formulæ for dyeing old batist articles a red-brown; for dyeing cotton-warp rags a rose-colour, and for producing yellow lists on woollen piece-goods dyed with Brazil-, log-, sanders-, and calliatur-woods; for a discharge with fuming nitric acid; for dyeing scarlet on flannel or woollen-yarn—in which there appears nothing novel; and for dyeing cotton-wool a black.

Anthracen Blue, an Alleged New Colour.—According to its reactions this is an ordinary aniline blue. Anthracen can produce tinctorial acids, such as alizarin, but not substantive basic colours.

New Iron Mordant.—Dissolve 200 grms. chromate of potash, 200 grms. oxalic acid, and 6 kilos. green vitriol, in 6 litres of water.

PATENTS.

ABRIDGMENTS OF PROVISIONAL AND COMPLETE SPECIFICATIONS.

Improvements in and connected with the manufacture of electrotypes.—James Noad, engineer, Hackney Wick, Middlesex. December 18, 1872.—No. 3839. A new material is used for forming the moulds, consisting of lead melted and mixed with roll-sulphur, ground fine, then mixed with gutta-percha or its equivalent. To copy type, this material is milled, brushed over with black-lead, then softened, and pressed on the type; afterwards it is put into a lead bath, and worked by a battery, then washed, and put in a copper bath, and backed. To surface, the mould is put into a sulphate of copper bath containing 7 per cent free acid, the bath is worked with a large anode, and rubbed during deposition.

Improvements in the estimation of metals.—Joseph Norman Lockyer, F.R.S., Finchley Road, Middlesex. December 18, 1872.—No. 3846. My invention consists in the application of the spectroscope to the estimation of metals.

Improvements in treating human excreta, and in apparatus for working the excreta and converting the same into a dry and highly concentrated manure.—William White Fereday, civil engineer, 5, Falmouth Road, Dover Road, Surrey. December 21, 1872.—No. 3882. This Provisional Specification describes a system of collecting night-soil, and converting it into manure in such manner that no effluvia is emitted or ammonia lost.

Improvements in the manufacture of asphalt for paving and covering roads and ways, and in the apparatus employed therein.—Alexander Prince, 4, Trafalgar Square, Charing Cross. (A communication from Peter Barthel, Ferdinand Capitaine, and Philipp Holzmann, all of Frankfort-on-the-Maine). December 21, 1872.—No. 3886. The novelty of the invention consists in dissolving natural asphalt in sulfurete of carbon or in benzine, by the application of heat, the solution of which, when passed through a sieve, is placed in a kettle heated by steam and a furnace, in order that the sulfurete of carbon or benzine held in solution may be evaporated, after which the asphalt is mixed with granular calcareous spar or marble, preparatory to its being used for the purpose desired.

An improved stopper for bottles.—Alphonse Krieger and Augustin Cauderlier, Boro', Surrey. December 21, 1872.—No. 3887. The stopper consists of a short tube of india-rubber, one end being closed and of bulbous form, to press against the inside of the neck of the bottle and make a tight closure. A head is provided to prevent the stopper being pushed too far into the bottle, and for handling the same.

An improvement in the process of unhairing and preparing skins or hides to be employed for making or dressing into leather of any kind.—Joshua Senior, foreman skinner, New Ross, Wexford, Ireland. December 23, 1872.—No. 3889. Hitherto lime has been used for this purpose, but in carrying out my invention I make use of soda-ash or any other alkaline solution in combination with lime. To 18 gallons of boiling water I add about 20 lbs. of soda-ash, which must be stirred till the alkali is completely dissolved; then, immediately afterwards, about 1 cwt. of fresh quick-lime must be thrown in gradually. It will then begin to boil fiercely, so that the pit-tank or any other suitable vessel should be sufficiently large to prevent it from boiling over. If, when done boiling, the solution is not all absorbed, a little more fresh lime may be added; when the mixture is quite cold it is ready for use, and should be of the consistency of soft clay. To each pit capable of containing or working fifty or sixty dozen of sheep pelts, from about 1 cwt. 2 qrs. to about 2 cwt. of the mixture, with a sufficient quantity of water, may be put in when making new.

Improvements in closets and apparatus for collecting and disinfecting fecal matters and converting the same into manure or human guano.—Leos Antoine Badin, civil engineer, New Ormond Street, Middlesex. December 24, 1872.—No. 3913. The first part of this invention relates to improvements in the arrangement and construction of water-closets for the purpose of preventing the water (used for washing the pæ) from mixing with the urine and fecal or solid matters. The second part of this invention relates to improved apparatus for receiving, treating, and filtering the urine and fecal matters as they are discharging from the water-closet or other source. Thirdly, in the application of a new chemical solution for the direct chemical treatment of urine in order to extract the salts (ammoniacal) which may be mixed with the solid matters, in order to increase the agricultural value of the manures thus obtained. Fourthly, in improved arrangement and chemical disposition of apparatus for the purpose of applying this improved system to urinals in order to treat the urine chemically. Fifthly, in improved means of preserving the manure when dried and pulverised, together with improved chemical combinations for fixing the fertilising principles which the organic matters contain, in order to avoid their destruction, which generally follows by decomposition (caused by fermentation).

NOTES AND QUERIES.

Crome-Yellow.—(Reply to "Colour.")—The yellow colour you refer to is tungstic acid made from tungstate of soda.—A. KIRKPATRICK AND CO., 27, Side, Newcastle-upon-Tyne.

TO CORRESPONDENTS.

* * Vol. XXVII. of the CHEMICAL NEWS, containing a copious index, is now ready, price 11s. 4d., by post, 12s., handsomely bound in cloth, gold lettered. The cases for binding may be obtained at our office, price 1s. 6d. Subscribers may have their copies bound for 2s. 6d. if sent to our office, or, if accompanied by a cloth case, for 2s. Subscribers wishing to complete their sets of volumes are requested to apply to the publisher, who will give them information respecting scarce numbers and volumes. Vol. xxviii. commenced on July 4th, and will be complete in twenty-six numbers. READING CASES, price 1s. 6d. each, post free, may also be obtained at the Office.

G. A.—We shall be happy to insert your letter if you conform to our rules and send us your address.

SUPPLEMENT TO THE CHEMICAL NEWS.

Vol. XXVII. No. 713.

INVESTIGATION OF THE FLUORESCENT AND ABSORPTION SPECTRA OF THE URANIUM SALTS.*

By HENRY MORTON, Ph.D.,
and H. CARRINGTON BOLTON, Ph.D.

AMONG bodies possessing a property which he named "internal dispersion," Sir David Brewster, in 1848, mentioned a glass of a greenish yellow colour. In his admirable treatise "On Fluorescence," published in the *Phil. Trans.* for 1852, Stokes describes the examination which he made of the light emitted from the glass, which he found to yield a discontinuous spectrum, and relates how, finding that the colouring material of this glass was the oxide of uranium, he proceeded to study other compounds of the same base.

The following is a list of the bodies thus examined:—

1. Nitrate of uranium, crystals and solution.
2. Yellow uranite (lime uranite).
3. Green uranite, or chalcilite (copper uranite).
4. Pitch blende.
5. Hydrate of peroxide of uranium, $U_2O_3 + 2HO$.
6. Acetate " "
7. Oxalate " "
8. Phosphate " "
9. Uranate of potassa.
10. " lime.
11. Solutions by means of alkaline carbonates.

This paper of Stokes was the first thorough discussion of the subject, and at once established the true character of fluorescent actions, which, though before observed in a few instances, were in no wise understood. The investigation is, indeed, a masterpiece in its originality, ingenuity, and thoroughness; but in science no work can ever be exhaustive, and thus even such a research as this leaves ground yet to be explored. The spectroscopic, as an instrument of precision, had not, in fact, at this time been thought of, while the general character of the spectra formed by the fluorescent light emitted by many of the above list of substances was discussed, as also the bands of absorption shown by some of them with transmitted light; no attempt was made to measure the exact location of bands, and to record accurately their relative positions in different compounds, and other matters of detail requiring precise measurements. It is, however, wonderful, notwithstanding this, how far progress was pushed even with the less perfect appliances then at command; and we shall have frequent occasion to refer to Professor Stokes's prior indications of actions which more refined instrumental appliances have enabled us fully to develop.

In 1859 Becquerel published in the *Ann. de Chim. et de Phys.*, 3rd series, vol. lvii., p. 101,† an account of observations made with his phosphoscope, and other methods involving the use of a spectroscopic, upon many bodies, including the following uranium salts:—

1. Nitrate of uranium.
2. Uranium glass, i.e., canary glass.
3. Double fluoride of uranium and potassium.
4. Perchloride of uranium, i.e., oxychloride of uranium.
5. Uranite.
6. Double sulphate of uranium and potassium.

Two drawings are given to indicate the position of the bright bands with reference to the Fraunhofer lines, the first representing the spectra of canary glass and uranic

nitrate, the other those of potassio-uranic oxyfluoride, uranic chloride, and the mineral uranite.

The existence of absorption-bands in crystals of uranium nitrate is also noticed, but no measurements or exact description is given. Indeed this work, which deals chiefly with phosphorescence, devotes but a small space to the subject we are now considering.

Various other brief discussions, such as that of Werther in the *Journ. fur Prakt. Chem.*, vol. lxx., p. 349,* in which the simple fact of fluorescence and the general colour of the emitted light is noticed in some salts of uranium and other bodies, appeared subsequently, but no other work of importance or extent was undertaken for some time after that of Stokes and Becquerel in reference to the uranium salts in their fluorescent relations.

This was about the condition of the subject when, in the spring of 1872, we undertook the accurate measurement and plotting of the fluorescent spectra of the uranium salts, preparing all the salts used ourselves so as to be confident of their purity.

A large number (over thirty) had been so studied, the results classified and discussed, and a memoir partly written, when, in the *Comptes Rendus*, August 5, 1872, we found the abstract, published by Becquerel, of a research covering very much the same ground. In the December number of the *Ann. de Chim. et de Phys.* for the same year appeared the entire memoir, in which were given the observations and measurements made upon eighteen salts.

Many of his conclusions were, however, different from those at which we had arrived, and we therefore determined to withhold our publication until these points of variance could be thoroughly re-examined. Such examination has confirmed our original results, and we therefore now publish our work as an independent research, which, of course, lays no claim to any of the results already obtained by Becquerel, but which will be of value as a combination of these, and will add to the knowledge of the subject in many directions, in which what we have done has been nowhere anticipated.

We should also state that Hagenbach, in his admirable series of papers on fluorescence, has given measurements of the spectra of canary-glass and uranic nitrate, *Pogg. Ann.*, vol. cxlvi., p. 393.

Methods Employed.

Our methods of examination do not differ from those employed by Stokes and Becquerel except in small details by which the labour of observation was facilitated, and by the means at our disposal for securing accuracy in the measurements. They have already been described by one of us, in connection with a similar investigation in which they were employed,† but to avoid trouble of reference, we will here briefly re-state them.

The general method pursued was as follows:—

Sunlight being reflected horizontally into a darkened room by a porte-lumiere was concentrated by a lens, and filtered of all rays below Fraunhofer's line F by a tank containing a strong solution of ammonio-cupric sulphate placed in front. Two tanks containing liquids of different concentration interchangeably used.

In the front of the lens was placed a little circular table carrying on its edge eight niches capable of supporting test-tubes or specimen bottles, and rotating with a "click," so that each of these could be readily brought into an identical position. The blue light falling on the specimen placed in one of these niches, the dispersed light was observed by means of a spectroscopic. The instrument most used in this work was a Browning single-prism spectroscopic, though one (by the same maker) with two prisms, and also a chemical spectroscopic of Deraga, were also employed in special cases. A direct-vision hand

† See also "La Lumiere," vol. i., p. 378.

spectroscope was also found very useful for preliminary observations and for recognition of faint absorption-bands.

For the study of the absorption spectra, the various pieces of apparatus were re-arranged so as to observe transmitted light, the rotating stand being replaced by a block or table, on which the objects were successively placed.

To observe solid substances in this way, various devices were employed. If a crystal of the requisite dimensions could be obtained, it was cemented to a plate of glass or mica, and supported vertically by means of a flat cork, in which the edge of the plate was sunken. Powders, such as the uranic oxalate, phosphate, &c., were mixed with a little water, and allowed to dry in a thin film on plates of glass or mica. In other cases, as with the double uranic sulphates, the salt was placed on a slip of glass and moistened with a very little water. Another similar glass was then placed upon it, and pressed down with a gentle rotary or grinding motion, by which the substance was reduced to small fragments in close proximity, which formed a film whose thickness could be graduated with ease. Gummed labels pasted over the ends of the slips kept all in place.

Solutions were examined either in bottles of white glass of about 1 oz. capacity (being 1 inch in diameter), or in small specimen bottles made from glass tubes whose diameter was only about $\frac{1}{4}$ an inch.

Other special arrangements, which were from time to time employed in particular cases, will be described in connection with the substances to whose examination they were adapted.

We hereto append a list of the substances which we have prepared, and whose spectra, both of fluorescence and absorption, we have carefully measured and mapped.

URANIUM COMPOUNDS OBSERVED.

<i>Acetates</i> —	Sodio-uranic oxyfluoride.
Uranic acetate bi-hydrate.	Uranous fluoride.
" " (anhydrous).	Sodio-uranous fluoride.
Ammonio-uranic acetate.	Potassio- " "
Bario- " "	<i>Formiate</i> —

In Fig. 1. we have given drawings of some of the most characteristic spectra of fluorescence and absorption. In these drawings the refrangibility of the light is indicated on the scale with millimetre divisions introduced for this purpose by Bunsen. This scale was selected for the double reason, that it corresponds very nearly with the appearance of the spectrum as seen in the spectroscope employed, which is one largely in use and peculiarly well adapted to such observations as the present, and that it is largely used in all chemico-spectroscopic work, and would therefore be most familiar to those likely to take interest in this work, which has a decided chemical affiliation.

The relative intensities of various parts of the bands, and of the bands of each spectrum among themselves, is indicated by the depths of the white spaces, the distinction between the bright bands of fluorescence, and dark bands of absorption, being marked by making the first white and the other shaded. No attempt is made to indicate the relative brightness of different spectra.

This woodcut is to be regarded, however, rather as an illustration than as a map in which various positions are to be found with great precision. From the nature of the work, correction after proof is limited to very slight variations, and the full difficulty of accurate execution did not appear until the work was finished.

The spectra, as here shown, will be found correct in the character and arrangement of the bands in each, but small errors in the location of the maxima of bands must be expected, and, in fact, for all points where precision is required, it will be necessary to refer to the exact numerical expressions.

As will be seen further on, the behaviour of absorption-bands is a very useful assistance and guide to the study of certain changes in these salts, and we have therefore given some attention to these, although a variety of considerations indicate that no such connection exists between the band of absorption and fluorescence in these salts, as would be at first suggested by their general similarity of arrangement.

A single glance at the woodcut will exhibit the existence of very characteristic differences between the spectra of certain salts, and it will be evident that, in a number of cases, one body can be readily discriminated from another by this means. Indeed, in the course of this investigation, the fact of admixture in many of the commercial uranium salts was recognised in this way, without opening the bottles in which the materials in question were packed, and, in other cases, the progress and consummation of a change in composition, or in the formation of a compound, was watched and recognised with the greatest ease and precision.

In almost every case there is a tendency of the light to fade off in the bands towards one side more gradually than towards the other. In nearly all spectra this gradation is greatest towards the less refrangible end of the spectrum.

The character of any one band is, as a rule, a type of all the bands of a spectrum; but to this a remarkable exception is found in the double acetates of uranium generally, and especially in the sodium salt whose fluorescence is the brightest.

In the spectrum of this salt the first four bands at the lower end of the spectrum in the orange and red differ entirely in character and spacing from the rest, except the fifth, which seems to be in a transition state. This will be seen at once by a glance at spectrum 3 of the woodcut.

It is also true, as a rule, that double salts with the same acid have bands of a like character; but to this also there are decided exceptions, and it is by no means true that all salts with the same acid—as, for example, acetates and double acetates, as stated by Becquerel—have like bands. This chances to be true in the case of

the sulphate and normal double sulphates, but in the case of the acetate and double acetates, fluoride and double fluorides, chloride and double chlorides, as also among the numerous hydrates of the sulphates, it fails to maintain itself.

A glance at spectra 4 and 5 on Fig. 1 will show that

FIG. 1.

1. Uranic nitrate. 2. Uranic acetate. 3. Sodio-uranic acetate. 4. Uranic oxychloride (acid), mixed hydrates. 5. Bario-uranic oxychloride. 6. Uranic oxyfluoride. 7. Bario-uranic oxyfluoride. 8. Uranic phosphate, mixed hydrates. 9. Calcio-uranic phosphate. 10. Ammonio-uranic sulphate.

nothing could well be more unlike than the spectra of uranic oxychloride and the potassium chloride.

The question naturally arises, how far the spectra of substances are constant, and in what way a change in spectrum if observed is to be interpreted.

To this we would reply that we have so far found that no substance has its spectrum changed by anything which does not affect its composition, excluding the effect of heat, which in all cases temporarily modifies fluorescent action, and the destruction of crystalline structure by fusion, which in some cases has a like effect permanently. We must also exclude certain cases in which, by peculiar treatment, a substance has been caused to give a continuous spectrum, in place of what may be considered its normal one.

We may, therefore, confidently assert in many cases whether (under certain treatment) a body has or has not suffered a change in composition, and, indeed, trace such a change step by step.

This part of the subject can be best elucidated by a narration of our experience in the first case in which this principle was applied.

Stokes had noticed certain effects in nitrate of uranium which had been fused and partly dehydrated, and after an

refrangible extremities of the scale. The following table will give some notion of these spectra:—

Fluorescent Spectra of Ammonio-Uranic Sulphates.

	I.	II.	III.	IV.	V.	VI.	VII.	VIII.
Normal salt	36°0	41°6	49°2	58°1	68°0	77°0	86°0	95°0
(hydrated) ..								
Dried salt (anhydrous) ..	33°4	40°0	48°0	56°3	65°7	75°2	86°0	92°8
Heated salt..	36°0	42°4	51°2	60°3	70°0	79°8	89°2	96°8

As also Figure 2, in which 1 is the normal salt, 2 the mixture of this and the anhydrate obtained by partial drying, 3 the pure anhydrate, 4 the mixture of this and the new salt obtained by partial ignition, and 5 the pure ammonio-di-uranic sulphate.

The white fumes expelled in the process of heating were ammonium sulphate, and the resulting compound yielding the new spectrum, therefore, might have been formed in one of two ways; either all the ammonium sulphate had been driven out, or a portion only. It became necessary, therefore, to test the heated salt for ammonia, which was done by distilling a portion with hydrate of calcium, and receiving the distillate in Nessler's reagent. The abundant precipitate obtained established the presence of ammonia in such quantity as to render the delicacy of the test applied quite superfluous.

The question then arose, Is this salt a definite compound of uranic sulphate with ammonium sulphate? Analysis alone could reply.

The heated salt possessed a somewhat stronger greenish hue than the normal salt; it was completely soluble in water with the exception of a few dark coloured grains, probably consisting of U_3O_4 .

For analysis the salt was dissolved in water, and the sulphuric acid thrown down by barium chloride; after separating the excess of this reagent in the filtrate the uranic oxide was precipitated by ammonia, ignited and weighed as U_3O_4 in the usual manner:—

0·6444 grm. gave 0·5284 grm. $BaOSO_3$ = 28·15 per cent SO_3 , and 0·4194 grm. U_3O_4 = 66·30 per cent U_2O_3 . The formula, $2(U_2O_3SO_3) + NH_4OSO_3$, requires the following percentages:—

	Calculated.		Found.
$(U_2O_3)_2$ =	288	66·36	66·30
NH_4O =	26	5·99	—
(SO_3) =	120	27·65	28·15
	434		

From this it is evident that one-half the ammonium sulphate in the normal salt is driven out by heating, leaving an anhydrous ammonio-di-uranic sulphate.

In his recent memoir Becquerel describes, under the name of a sub-ammonio sulphate of uranium, a salt obtained in the preparation of nitrate of uranium from impure materials, and states that it is the only uranium compound whose fluorescent light yields a continuous spectrum. The composition given by him (U_2O_3 4 parts, SO_3 2 parts, ammonia 1 part), unless regarded as a mere rude approximation, would agree better with a mixture of several salts than with any probable formula of an ammonio-uranic sulphate. This may, however, be a case of what may be called the abnormal continuous spectrum already alluded to.

We have found uranium compounds yielding continuous spectra, but the true sub-ammonio sulphate—or, rather, ammonio-di-uranic sulphate—does not appear to belong to that class.

(To be continued.)

FIG. 2.

attempt to reproduce his results, the ammonio-uranic sulphate was in turn treated in a like manner.

A little of the crystallised salt containing 2 atoms of water was placed in a short test-tube, and heated until part of its water had been expelled. On examination (after cooling, for while hot little fluorescence was manifested) its spectrum was found to be of a duplicate character, consisting of the bands belonging to the normal salt, and another set, each line of which was a little displaced downwards in the spectrum. On heating again and expelling more water, the intensity of the new spectrum was increased, and that of the old one diminished; and this continued until—when water ceased to come off—the new spectrum alone occupied the field. It was, therefore, concluded that this was the spectrum of the anhydrous salt.

On now pushing the heat further white fumes were expelled from the salt, and on examination—in addition to the spectrum just described—yet another new one was perceived, having its bands displaced upwards in a very marked manner. Further heating drove off more white fumes and strengthened this new spectrum, while it diminished the one proper to the anhydrous salt, until at last fumes were no longer expelled even at a temperature of about 650° F., and the last spectrum in turn occupied the field alone. It was then seen to be like the spectrum of the normal salt in character, but with its bands displaced upwards in a degree increasing from the less to the more

THE CHEMICAL NEWS.

VOL. XXVIII. No. 714.

ON THE PRESENCE OF CYANOGEN IN BROMINE.

By T. L. PHIPSON, Ph.D., F.C.S., &c.

I HAVE lately discovered in bromine issued as pure for pharmaceutical use, a notable amount of cyanogen. It has been known for many years (and I have myself alluded to it in another place) that during the manufacture of iodine a certain quantity of that most beautiful, but dangerous, compound, iodide of cyanogen, sometimes finds its way into one of the glass condensers; and it would appear, from the experiments to which I now allude, that a similar compound with bromine may occur in this liquid element—a more serious case than the other, since it is dissolved and masked in the liquid.

The presence of cyanogen in bromine may be detected in the following manner:—Take an equal weight of iron-filings (say $\frac{1}{2}$ oz.) to that of the bromine, and add to the iron-filings four or five times their weight of water; mix in the bromine very gradually, and stir all the time, filter rapidly while warm from the reaction, place the filtered liquid in a partially closed bottle, and in the course of some hours a deposit of ferricyanide of iron (Berlin blue) will have formed, and may be collected on a filter. In the course of two days (with the above quantity) the whole of the cyanogen is thus eliminated.

In the samples of bromine hitherto examined, I estimate there has been from 0.5 to 1 per cent of cyanogen in round numbers, and I am rather inclined to believe that this substance is often present in commercial bromine. If perfectly pure bromine be used, the same reaction would enable us to detect cyanogen in steel.

ON THE ESTIMATION OF MAGNESIUM AS PYROPHOSPHATE.

By WOLCOTT GIBBS, M.D.

ALL works on quantitative analysis recommend the precipitation of magnesium in the form of ammonio-magnesian phosphate, from cold solutions, by disodic phosphate. I find it more convenient, if not more accurate, to employ microcosmic salt as a precipitant, and to precipitate from concentrated and boiling solutions. After cooling ammonia is to be added, and the process then continued in the usual manner. The following analyses were made under my direction by Mr. C. E. Munroe to test the method. In the first series pure magnesian sulphate was precipitated at a boiling heat and in concentrated solutions by microcosmic salt, no ammoniac chloride being present.

1.	0.6430 gr.	gave	0.2914 gr.	$Mg_2P_2O_7$	= 9.85
2.	1.1523	"	0.5210	"	= 9.79
3.	0.7064	"	0.3181	"	= 9.78
4.	0.8081	"	0.3666	"	= 9.80

The formula $SO_4Mg + 7OH_2$ requires 9.76 per cent. The mean of the four analyses is 0.04 per cent too high. In a second series the same process was employed, but ammoniac chloride was added to the magnesian solution before precipitation. In this manner:—

5.	0.5448 gr.	gave	0.2461 gr.	$Mg_2P_2O_7$	= 9.76
6.	0.6684	"	0.3026	"	= 9.78
7.	0.7610	"	0.3442	"	= 9.78
8.	0.6408	"	0.2906	"	= 9.79

The mean of the four analyses gives 9.78 per cent, or 0.02 per cent too high,

Two analyses were then made by precipitating the boiling solution of disodic phosphate after adding ammoniac chloride. In this manner:—

9.	0.5407 gr.	gave	0.2536 gr.	$Mg_2P_2O_7$	= 10.13 per cent.
10.	0.8305	"	0.3881	"	= 10.10 "

This method must therefore be wholly rejected, the mean error being +0.35 per cent.

The same process was then repeated, only the precipitated ammonia-magnesian phosphate at first obtained, after addition of ammonia water and perfect subsidence, was re-dissolved in dilute chlorhydric acid, and again precipitated by ammonia. In this manner:—

11.	0.5916 gr.	gave	0.2686 gr.	$Mg_2P_2O_7$	= 9.79 per cent.
12.	0.7371	"	0.3340	"	= 9.79 "

The error is here only +0.03 per cent, but the method is longer in its application and less convenient than that given above with microcosmic salt. This last may, I find, be used with equal advantage in precipitating manganese from hot solutions. The precipitate is crystalline, and the process is more convenient than that which I formerly gave. A little ammonia should be added to the solution before filtering.

On the Estimation of Cobalt.—The extraordinary stability of the cobaltid-cyanide of potassium, $Co_2Cy_{12}K_6$, enables us to separate cobalt advantageously from many other metals by bringing it into this form. Wöhler first proposed to precipitate the double cyanide by mercurous nitrate, and to weigh the cobalt finally as metal. I find it particularly advantageous to precipitate at a boiling heat, and then boil for a few minutes with mercuric oxide, so as to neutralise as completely as possible any traces of free nitric acid. By precipitating from hot solutions a granular, crystalline, mercurous salt is obtained, which is very readily washed. The following analyses were made to test the method. In (1) and (2) the precipitation was effected at a boiling heat, and the precipitate was simply washed with hot water containing a little mercurous nitrate. The cobalt was, after careful ignition with free access of air, finally reduced in hydrogen. The salt employed was pure crystallised $Co_2Cy_{12}K_6$.

(1).	0.5063 gr.	gave	0.0890 gr.	cobalt	= 17.57 per cent.
(2).	0.6785	"	0.1197	"	= 17.64 "

The filtrate, after evaporation to dryness and ignition, gave with borax, before the blowpipe, an extremely faint reaction for cobalt. In analyses (3) and (4) the solution was boiled with HgO in small excess before filtration.

(3).	0.5332 gr.	gave	0.0947 gr.	cobalt	= 17.76 per cent.
(4).	0.6218	"	0.1101	"	= 17.71 "

In (5) mercuric chloride was first added to the solution, and afterward sodic hydrate, until HgO remained undissolved on boiling.

(5).	0.5855 gr.	gave	0.1035 gr.	cobalt	= 17.68 per cent.
------	------------	------	------------	--------	-------------------

The formula requires 17.76 per cent.

ON THE SO-CALLED "REDUCED" PHOSPHATE AND THE VALUATION OF OLD COMMERCIAL FERTILISERS.

By CHARLES U. SHEPARD, Jun., M.D.

IN view of the great consumption of commercial fertilisers in the Southern Country, it may be deemed proper to devote a few pages of this journal to the consideration of certain questions involved in the valuation and use of superphosphates. Although the writer feels that this article leaves much undone, to the consideration of which points he intends returning on the completion of other experiments, still he is led to publish the results of some investigations, carried on in his laboratory, in answer to the wishes of certain friends of agriculture and agricultural chemistry.

The basis of the superphosphates employed in this region is, pre-eminently, the South Carolina phosphatic rock, an impure phosphate of lime. It consists of about 55 per cent phosphate of lime, 5 to 10 per cent carbonates of lime and the protoxide of iron, a few per cent oxides of iron, and traces of magnesia and alumina, partially combined with phosphoric acid; the remainder being unimportant for our present study. The phosphate of lime is, in all probability, entirely of the character of the so-called bone phosphate, or basic phosphate of lime, i.e., the chemical compound of 1 atom of phosphoric acid and 3 of lime. This form of phosphoric acid, the one important for vegetable and animal life, requires 3 atoms of base, whether they be metallic oxides (as lime) or simply atoms of water. The basic phosphate of lime is, practically considered, insoluble in water (especially in its mineral state), as is also the neutral phosphate of lime, a compound of 1 atom of phosphoric acid, 2 of lime, and 1 of water. On the other hand, the acid phosphate of lime, a compound of 1 atom of phosphoric acid, 1 of lime, and 2 of water, is highly soluble in water. The "free" phosphoric acid, also quite soluble, is an atom of this acid with 3 atoms of water joined chemically to it.

Dr. Piccard has shown (in the Swiss *Polytechnical Journal*)—(1). That a complete solution of 1 equivalent of basic phosphate of lime is produced by the addition of not less than 2 equivalents of hydrated sulphuric acid, (i.e., 2 equivalents of hydrated sulphuric acid act on 1 equivalent of basic phosphate of lime to produce 2 equivalents of gypsum and 1 of acid phosphate of lime, substances readily soluble in water)—

The excess of water ordinarily present furnishes the requisite quantity of water to produce 2 equivalents of hydrated sulphate of lime, $\text{CaO},\text{SO}_3 + 2\text{HO}$.

(2). By the action of more than 1 and less than 2 equivalents of hydrated sulphuric acid upon 1 of basic phosphate of lime, either of the following cases may occur:—

(a). Where only 1 equivalent of sulphuric acid is taken, and subsequent changes in the mixture are arrested by an early separation of the soluble and insoluble portions; in this case one-half of the basic phosphate of lime is converted into acid phosphate of lime and gypsum. (b) Where the mixture is allowed to stand for a long time, and opportunity is thus afforded for the completion of chemical reaction, the acid phosphate of lime (formed from one-half of the basic phosphate by the action of the acid) reacts upon the remaining undecomposed basic phosphate, producing the intermediate neutral phosphate of lime, $\text{CaO},2\text{HO},\text{PO}_5 + 3\text{CaO},\text{PO}_5 = 2(2\text{CaO},\text{HO},\text{PO}_5)$.

In his studies concerning superphosphates,* R. Jones, assistant at the Kuschen Experimental Station, comes to the following conclusions as the result of a long series of interesting and careful experiments:—

(1). The superphosphates are not unchangeable mixtures of gypsum, acid phosphate, and undecomposed basic phosphate of lime; but they contain the soluble phosphoric acid in the form of free phosphoric acid and acid phosphate of lime, the insoluble phosphoric acid as basic and neutral phosphate, and, in rare cases, in combinations which stand between the neutral and acid salts. Sulphuric acid is contained in them in the form of gypsum, and only exceptionally do any considerable quantities of free sulphuric acid appear to occur in them.

(2). These different chemical combinations are undergoing a constant interchange of elements; which decompositions produce, according to the external conditions and the quantity of sulphuric acid employed, an increase or a decrease in the amount of soluble phosphoric acid.

(3). A decrease takes place in every superphosphate, independent of the amount of sulphuric acid employed, where it loses in water, either by the action of artificial heat, or from long exposure to dry air. Again, "going

back" (or the conversion of phosphoric acid from soluble into insoluble forms) takes place, independent of the amount of water which they contain, in such superphosphates which contain a large amount of basic phosphate of lime, in consequence of the employment of an insufficient quantity of sulphuric acid.

(4). An increase in the amount of the soluble phosphoric acid can only take place where, in consequence of the use of large quantities of sulphuric acid, the insoluble phosphate of lime contains more phosphoric acid than is present in the neutral phosphate.

The preceding observations have reference, it is true, more especially to the continental high-grade superphosphates, which, when freshly manufactured, contain from 10 to 25 per cent of soluble phosphoric acid, equivalent to from 20 to 50 per cent of bone phosphate dissolved, but they apply also to the articles prepared and sold in America. These latter, being manufactured from articles containing basic phosphate of lime, carbonate of lime and iron, oxides of iron, magnesia, and alumina (partially joined to phosphoric acid), present for our study causes of a reduction of the soluble phosphoric acid other than the large amount of originally unacted-upon basic phosphate of lime, always present in superphosphates prepared from South Carolina rock by the application of a comparatively small quantity of sulphuric acid. In this case, whatever carbonate may have remained undecomposed will most likely suffer decomposition from the action of acid phosphate of lime, the results being the liberation of carbonic acid and the substitution of the metallic oxide (previously combined with carbonic acid) for atoms of water in the acid phosphate; thereby reducing it to the insoluble condition. Whatever free alumina or peroxide of iron may be present in the superphosphate acts in a similar manner. Where sulphate of iron or alumina have been formed by the action of sulphuric acid, there is no reason to fear a *direct* exchange of elements between them and the acid phosphate of lime. At another time I hope to speak of the modifications of these reactions produced by the liberal use of alkaline chlorides.

Having thus endeavoured to introduce some of the causes for the decrease in soluble phosphoric acid of old superphosphates, I would here call attention to various methods which have been employed to determine the degree of reduction. It is well to state that the desideratum is a method by which the amount of the decomposed phosphate of lime in a superphosphate can be determined; the soluble phosphoric acid having been previously extracted by water. This decomposed phosphate, whether wholly or partly a lime salt, may be either the neutral or the precipitated basic phosphate. It is requisite that the solvent for the decomposed phosphate shall not attack to any considerable extent the undecomposed phosphatic basis of the superphosphate, otherwise the results are indeed questionable. The weaker vegetable acids* have been recommended as fit solvents for the reduced phosphates, but they are liable to the above objections. Again, the ammoniacal salts of carbonic and certain vegetable acids† have been used for a like purpose. Without entering upon a detailed criticism of the results of the treatment of superphosphates and pulverised raw phosphates by other chemists, nor upon my own investigations in this direction, I would mention that the bicarbonate and succinate of ammonia do not dissolve the neutral and freshly precipitated phosphate in a sufficient degree to allow of their use. The oxalate of ammonia is an admirable solvent of these phosphates, but, unfortunately, it attacks the raw basic phosphate so as to vitiate the analytical results. The neutral citrate of ammonia, however, while it dissolves nearly entirely the neutral and

* J. A. Chesshire, *CHEMICAL NEWS*, July, 1869.

John Hughes, *Ibid.*, August, 1869.

Francis Sutton, *Ibid.*, October, 1869.

† Dr. J. König, *Annalen der Landwirtschaft*, bd. 58.

Dr. Fresenius, *Zeitschrift für Analytische Chemie*, 1.

* *Annalen der Landwirtschaft*, b. 56.

freshly formed basic phosphates of lime (as also those of alumina and iron, König) dissolves but very slightly the finely ground mineral phosphate.

Thus König found by boiling for one half hour a weighed amount of ground Lahn phosphorite, rock not dissimilar to South Carolina phosphate, in a sufficient quantity of neutral citrate of ammonia, that less than 2.50 per cent of phosphoric acid, or about $\frac{1}{10}$ th of that in the rock, was taken into solution. On the other hand, Fresenius, who does not allow the temperature of the mixture to reach blood-heat, did not dissolve more than $\frac{1}{10}$ th of the phosphoric acid. The difference in these results may be due to the difference in the temperature of the neutral citrate of ammonia while acting upon the phosphate.

In the following determinations of reduced phosphate I followed the method prescribed by Dr. Fresenius in his *Journal of Analytical Chemistry*, and published a year ago.

(1). My first object was to ascertain the effect of the neutral citrate of ammonia upon the finely ground mineral phosphate. To this end a sufficient quantity of the reagent was allowed to act upon the fine phosphate for half an hour at a temperature of about blood heat.

Material A.—Sample of the phosphatic dust from over the mill stones of the Stono Works, kindly furnished me by Dr. St. Julien Ravenel.

B.—Sample of a cargo of Coosaw River phosphate, ground exceedingly fine by hand. This cargo had been ascertained to contain 27.20 per cent phosphoric acid by Dr. Aug. Voelcker, of London:—

	Before Treatment.	After Treatment.
A. PO ₅	26.86 W.	24.28
„	27.22 W.	24.22
Average	27.04	24.25
B. PO ₅	27.29 S.	—
„	27.12 W.	—
Average	27.20	24.75

The analytical results marked with W. are by my assistant, Dr. W. D. Wamer; those with S. are my own. The determinations of phosphoric are always, unless it is stated to the contrary, by the molybdate of ammonia method.

The above analyses give a difference of 2.79 per cent for A, and 2.45 per cent for B, in the amounts of phosphoric acid before and after treatment with the neutral citrate of ammonia. Bearing in mind the low temperature of the above digestions, the probability seems warranted that, in this finely divided condition, the South Carolina phosphate is soluble to the extent of 1 part in 10 to 12 in the reagent employed. If these figures are corroborated by additional analyses which I propose instituting at an early day, the greater value of these local phosphates will be established, since they will be shown to be easier decomposed by the weaker class of solvents.

It must be remarked, however, that the physical condition of the material acted upon was, from its extreme fineness, remarkably adapted for the action of the solvent; much more so than the coarser ground rock which serves as the base of the ordinary superphosphate.

(2). A number of ammoniated superphosphates which had been manufactured during the fall and winter of 1870-71, and analysed at that time by me, were subjected to a second analysis during the past winter, more especially with a view of ascertaining the condition of the phosphoric acid in them.

The first determinations of phosphoric acid were executed by the protochloride of uranium method, as is customary in this laboratory with freshly prepared fertilisers; the subsequent ones by the molybdate of ammonia method, with the exception of those for the soluble phosphoric acid, which were made by the previous method.

The articles examined were:—

A. Superphosphate containing a very small quantity of fish scrap.

B. Superphosphate ammoniated with a larger amount of fish scrap and with Peruvian guano.

C. Superphosphate ammoniated as the previous one.

D. Superphosphate ammoniated with dried flesh and guano.

	Analyses in 1870-71, Phosphoric Acid.		Analyses in 1871-72, Phosphoric Acid.			Loss in Soluble Acid.	Excess of Reduced over Loss in Soluble.
	Soluble.	Insoluble.	Soluble.	Reduced.	Insoluble.		
A.	3.74	—	3.34	2.19	14.70	0.40	1.79
B.	2.68	11.73	2.55	1.85	13.12	0.13	1.72
C.	4.38	8.43	3.42	2.32	9.27	0.96	1.36
D.	4.31	8.72	3.45	2.91	10.70	0.86	2.05

In nearly every case the percentage of total phosphoric acid in the old fertiliser will exceed that in the new by from 2 to 3 per cent; this increase being due to the loss of moisture, which ranges from 10 to 15 per cent in the ordinary superphosphates, as a result of their being kept through the hot summer.

Additional analyses of samples of various fertilisers kept in my laboratory for several years show similar results.

E. A superphosphate analysed in spring, 1869.

F. Ditto, ammoniated with flesh, analysed in summer, 1869.

G. Ditto, ammoniated with sulphate of ammonia, male and analysed in winter 1869-70.

H. A superphosphate which, while in bulk, was thoroughly drenched by a freshet in the fall of 1870, kindly furnished me by Dr. St. Julien Ravenel.

	(1). Analyses, S. Phosphoric Acid.		(2). Analyses, W. Phosphoric Acid.			Loss in Soluble Acid.	Excess of Reduced over Loss.
	Soluble.	Insoluble.	Soluble.	Reduced.	Insoluble.		
E.	5.86	8.26	3.95	4.35	5.70	1.91	2.44
F.	4.55	10.27	3.68	3.85	8.78	0.87	2.98
G.	5.54	—	2.93	4.26	11.67	2.61	1.65
H.	—	—	—	2.53	10.02	—	—

The preceding analyses indicate very clearly the truth of the theories advanced with regard to the method of reduction of the soluble phosphoric acid, which process takes place pre-eminently at the expense of the mineral basic phosphate of lime. For, even allowing a solubility of the mineral phosphate in the neutral citrate of ammonia, to the same extent as we observed in the cases of the very finely powdered phosphate, *i.e.*, $\frac{1}{10}$ th to $\frac{1}{12}$ th of the amount of phosphoric acid, there is still in most of the analyses a considerable quantity of reduced phosphoric acid in excess over the difference between the two determinations of soluble phosphoric acid, *i.e.*, over the loss of phosphoric acid; or, in other words, the amount of reduced phosphoric acid is greater than the sum of the loss in soluble acid, plus that amount of acid which we have reason to believe would be taken up by the reagent employed.

Perhaps at another time we may return to this subject. At present we call attention to a few considerations which must have weight in the valuation of all old superphosphates.

As a result of the completed chemical action there will be a larger amount of decomposed phosphate in the old fertiliser than in the new. This decomposed phosphate consists of a smaller amount of soluble phosphate, and a larger amount of phosphate insoluble in water but soluble in the reagents which in their action nearest approach the processes of the soil.

Jones found, in his investigations above cited, that the different phosphatic bases on being treated with sulphuric acid in proportion to their percentages of phosphoric acid (as also of carbonate of lime contained in them) afforded different results. Thus, old superphosphates made from Navassa burnt bone, and a mixture of the latter with phosphorite contained a comparatively large amount of neutral phosphate of lime; while those manufactured from Baker's Island guano and the Spanish phosphate contained less neutral and more decomposed basic phosphate of lime; the larger amount of neutral phosphate in the former being most likely produced by the action of the reducing agents before mentioned (especially the oxides of iron) on the acid phosphate of lime.

Bearing in mind the greater richness in phosphoric acid of the neutral than the basic phosphate, since for the same amount of lime it contains nearly one-third more phosphoric acid, and its solubility in weak reagents, it is not strange that Picard should have expressed himself as follows:—"It is hence impossible to estimate their value (superphosphates) by their percentage of soluble phosphoric acid, since one which is deficient in phosphate soluble in water can contain much which is decomposed. Therefore it follows—what at first appears paradoxical—that the value of a superphosphate as a manure is raised by the decrease of its percentage of soluble phosphoric acid, which, as is well-known, is contrary to the ordinary usage in estimating the value of a fertiliser."

Does, then, in our experience, a superphosphate diminish in value by remaining in store for a year or even longer? In the absence of the direct answer, which must come from the agriculturist, the following considerations will have weight in forming an opinion on the subject. And since the pure superphosphates are used to only a small extent, comparatively, in the South, we will consider at once some of the changes produced in an ammoniated superphosphate, such as is generally employed, by being kept over a season:—

(1). There is a relative gain in weight of the valuable ingredients from a loss of a greater or less quantity of moisture. (2). The ammoniacal matter suffers a moderate decomposition, by which it is made more easily assimilable by the plant, without losing much, if any, ammonia; provided a sufficient quantity of sulphuric acid was originally employed. (3). As a result of the effects of heat and pressure the fertiliser becomes more uniform in composition, and is physically improved by the disappearance of the small particles of mineral and organic matter. (4). There is a loss in the amount of soluble phosphoric acid, whether free or combined, and an increase in that of the phosphates soluble in those reagents which approximate the solvents of the soil.

It is unnecessary here to dwell upon the well-known precipitation out of solution of phosphoric acid and phosphate of lime, in every well-drained and chemically considered normal soil. It is in view of this fact that chemists regard the chief function of sulphuric acid in a superphosphate to be that of disintegrating the mineral phosphate, so that, when the article is brought into the soil, the then precipitated particles of phosphate can be readily absorbed by the plant. The ultimate action of the acid in some cases, as may be inferred from the preceding pages, is little else than that of a complete chemical subdivision.

On the other hand, the solubility of a salt renders its equal distribution through a soil much more perfect than the most careful system of manipulation can produce with an insoluble one, and this is, perhaps, the great advantage derived from the use of a highly soluble phosphate. Whether this physical and certain chemical advantages, such as its quicker reaction on, and liberation

* The writer cannot, without further experiment, indorse this opinion, since the circumstances which led Dr. P. to this statement are widely different from those in America. Dr. P. has reference undoubtedly to superphosphates which contain originally much more soluble phosphoric acid than those used here.

of, the dormant nutritive elements of the soil, more than compensate for the advantages above enumerated, we must leave to be answered by comparative field experiments. I will add that, so far as I have been able to learn, the experience of the planters has shown no difference between the effects of freshly prepared and old fertilisers.

The statements of M. Alfred Dudouy* are the only authority on this subject which I have been able to collect from the foreign journals. In his article "On the Superphosphate of Lime and its Manifold Effects," he writes:—

"A commencement has been made in France to use the precipitated phosphate or the neutral phosphate,† which offers the phosphate of lime to the plant precisely in the condition in which the acid phosphate returns for absorption by the spongioles of the radicles. We have had comparative experience which has shown to us the good effects of the precipitated phosphate, effects at least as pronounced as those of the acid phosphate, the amounts of phosphoric acid applied being the same. This equality of effect must, in our estimation, depend on the minute division of the precipitated phosphate, and also upon the nature of the soil previously well manured, and thus containing a large quantity of carbonic acid, and of potash ready for assimilation. But still we give our preference to the acid phosphate of lime, and for these reasons." The reasons are those previously mentioned by me. In conclusion, then, we can expect good results from the use of precipitated or reduced phosphates in a soil rich in organic matter, and thus capable of affording a large amount of carbonic acid, the great solvent of plant food.—*American Chemist.*

ON THE ENERGIES OF THE IMPONDERABLES, WITH ESPECIAL REFERENCE TO THE MEASUREMENT AND UTILISATION OF THEM.*

By the Rev. ARTHUR RIGG, M.A.

(Continued from p. 30).

LECTURE II.

The Energy of Gravity, with especial reference to the Measurement of it.

THE energy of gravity is one of the most silent and all-pervading of the energies of the imponderables. Although we may not be conscious of the fact, there need be no doubt that, were this energy to cease, we should be like those whom Milton describes as

"Upwhirled aloft
And sent transverse, ten thousand leagues away,
Into the devious air."

This calamity is averted by gravity putting forth that energy allotted to it by the Creator, and the work thus done enables us now to sit at ease, and gives us houses in which to dwell.

If, then, it be asked, where do we find this energy? we may say, "Look around." In this room, gravity, inasmuch as we are at rest, produces but a static action; there is, however, a clock ticking, and there gravity is producing motion. The combined harmonious operations of the energies of gravity and vitality brought us together this evening. Thus it has been ever since the creation of man; and yet there is good reason for the surmise that the energy of gravity, even if known, was little regarded in the earlier ages of the world. A history of observations

* *Journal d'Agric. Pratique*, No. 13, 1872.

† The neutral phosphate of commerce is a precipitated phosphate, formed by the precipitation of soluble phosphate with burnt lime or the carbonate of lime. Dr. N. A. Pratt has recently kindly furnished me with a sample of precipitated phosphate of lime, as prepared by his patented process. The percentages of phosphoric acid and lime in this article have been found, in my laboratory, to coincide pretty nearly with the formula $2\text{CaO}, \text{H}_2\text{O}, \text{PO}_3$, or the neutral phosphate of lime. I have prepared for my own experiments this same salt by the action of chloride of calcium in excess upon the common phosphate of soda.

on the energy of gravity, or even of traces of the recognition of this energy in these ages, has yet to be written. Whether, by some of the early Greek writers, gravity was supposed to be a power innate, as a living principle—a spirit in every particle of matter; or whether this power had a residence at the centre of the earth; or whether it resided in an atmosphere surrounding each particle of matter; or whether Seneca, who lived about 38 A.D., was moved, by a consideration of (to him) that mysterious principle we call gravity, to notice that the tides and the moon were somehow related, need not this evening concern us.

From the time of Seneca we may pass over more than fifteen hundred years, to the days of Galileo (A.D. 1600), who was perhaps the first person to notice that bodies in falling moved faster and faster. He attributed this to the effects of gravity, and considered that if he could retard speed whilst still permitting gravity to act, he might determine the law of increasing spaces in equal successive times. This he did by permitting a ball to roll down an inclined plane; friction on the plane caused the retardation, whilst gravity alone caused the motion. Thus he obtained the ratio of spaces in reference to succeeding times; but he made no attempt to measure the absolute spaces when a body fell freely.

Next to Galileo, in order of time, must be placed Kepler, a German astronomer, who, about 1615, in his search after certain astronomical relations, existing apparently through the mutual attraction of the planets each on the other, was led to surmises respecting the universality of the mutual influences of material bodies.

The succeeding fifty years present a blank in reference to inquiries or investigations respecting gravity. Then came Robert Hooke, who was at the same time a mathematician, an astronomer, and a mechanician. He was secretary to the Royal Society of England, and, from 1669 to 1674, seems to have frequently turned an inquiring mind to the nature of that influence which he thought he could observe to be exercised by the sun and earth upon others of the planetary system.

The great, and now (1873) universally recognised, law upon this subject was first laid down by observations and reasonings of Sir Isaac Newton, which, even at this day, are regarded with an almost religious veneration by the advanced and intelligent men of every nation. Although it is said that Newton began in 1670 to form more clear conceptions of the law of gravitation than had been propounded by any of his predecessors, we must remember on what surmises he had to build.

Kepler, about 1615, and Robert Hooke, about 1666, had led Newton, so early as the above-named date (1670), to form these conceptions, and it is probable that he was confirmed and directed in his anticipation by the fact that Richer noticed, in 1672, that a pendulum conveyed from Paris (lat. 48 deg. 50 min. N., long. 2 deg. 20 min. E.) to Cayenne, in South America (lat. 4 deg. 56 min. N., long. 52 deg. 20 min. W.) did not vibrate in the same time. This recorded fact was as a demonstration to the mind of Newton of the deviation of the figure of the earth from perfect sphericity, and its oblateness, or compression at the poles. It was not, however, until the publication of his "*Principia*," in 1687, that the law of gravitation was fully established and enunciated.

Briefly expressed, the law, as anticipated by others and propounded by Newton, is this—that the attraction of one planet upon another depends upon the masses (not upon the "weights") and distances of the two planets; not, however, is the law of increase or decrease such, that at one half of a distance or double of any distance is the intensity of the attractive force doubled or halved. This might be a first impression. Astronomical facts refused to conform themselves to such a law. They rebelled. The parliament of planets had prescribed another code for the inter-relationships of their mutual attractiveness, and although it might per-

haps have been readily inferred that, as the distance between the attracting bodies was increased, the intensity of attraction would be decreased, yet the law of that decrease was the one which Sir Isaac Newton announced. It is this—that if there be two heavenly bodies, say, the earth and the moon, and that these at a known distance are mutually exerting a certain attraction or drawing each to the other; then, if the distance be doubled, the influence will only be one-fourth of what it was. If the distance be trebled, then this influence will become one-ninth of what it was; if quadrupled, then one-sixteenth of what it was. Expressed in precise phraseology, the law of gravitation is that of the inverse square of the distances. Thus far satisfied the requirements of astronomers.

It is remarkable how much of the utilised information men possess has been derived from the observations of astronomers. The mechanism of the universe was known before Harvey discovered the circulation of the blood, or Watt constructed a steam engine. The astronomers seem to have been the pioneers of every branch of human knowledge. The Old and the New Testaments open astronomically. "In the beginning God created the heaven and the earth" (Gen., i., 1). "The wise men from the east came to Jerusalem, saying, where is He that is born King of the Jews? for we have seen His star in the east" (Matt., ii., 2).

It must be remembered that the science of astronomy in one important respect differs from all other sciences. Astronomers are observers only—they ascertain causes by watching effects. They cannot interfere with or alter the causes in operation. They cannot make experiments. That man presumed too much upon the powers of his astronomical friend who, having invited him to bring some of his acquaintance to see an eclipse of the moon by the aid of a telescope, and, arriving too late, assured those who accompanied him that the astronomer was not only a personal friend, but also a very kind-hearted man, and he did not doubt that the eclipse would be done again in order that they might see it. Yet upon these observers all experimenters erect their fabrics. The gigantic and uncontrollable phenomena, and all the laws of the universe of planets—of the ebb and flow of the tides, of meteorology, of terrestrial magnetism and its connection with the sun, are the results of observation. They could never have been known by experiment; indeed, we could not so interfere with them as to make an experiment. Remember, experiment is an interference on our parts, and a re-directing of energy into a new channel, in order that that may be observed which cannot otherwise be observed. Hence, if we wish to utilise observation it must be by the adaptation of an experiment in the presence of an observation—to contrive, in fact, a system of apparatus which may enable us to take observations, and at the same time to so control the elements of an experiment as to bring them within the range of our means of observation.

Such combination of experiment and observation is to occupy much of our attention this evening, as on the records of these men—Cavendish, Atwood, Kater, Sabine, and Baily, especially Captain Henry Kater, are built our system of measures and weights; for to them we are indebted for what must constitute a court of final appeal, should the time ever come when our present standards, being totally lost, it is essential to re-establish them.

The energy of gravity is peculiar, and differs from those other energies with which we are to be concerned, in that it seems inexhaustible—its power is not proportioned to the work it does. All other energies are in process of exhaustion by work when that work is measured by motion; not so gravity. Imagine a large ball, and a second small one, which gravitates towards it—the number of these small balls may be increased, and still the influence of gravity on each ball is as intense as though there was only one small ball; no exhaustion from work done affects the energy of gravity, and yet it

seems not to have any power of recouping its expended energies. There is no elasticity about it—at least, none in the hands of men.

For example, we can, in food, avail ourselves of affinity, and so, through the agency of assimilation, revive the energies of an exhausting vitality. Electricity can, upon a system of relays, or upon its extraordinary property of induction, renew at a distance, not only its pristine vigour, but an energy many-fold greater than its original one. Light can have its intensity and purity restored by heat. Gravity remains in its solitariness. True, we believe that vitality, affinity, electricity, light, and heat are independent of, and beyond the influence of, gravity; yet we know them not—we cannot bring them within the ken of our senses, except when they are associated with what owns the dull, dead, inert, and yet powerful influence of the energy of gravity. For all means yet employed have failed to develop or detect the presence of these imponderables in a *perfect vacuum*.

This fact seems to give support to the suggestion that the "potential energy of gravitation may be, in reality, the ultimate created antecedent of all motion, heat, and light at present existing in the universe."

The mode in which we estimate or measure gravity is peculiar. It is the only one of those energies with which this course of Cantor lectures has to deal that tells its story upon a scale-beam or spring balance. No concentrated rays of a tropical sun have ever caused an appreciable deviation of the most delicate balance; neither light nor heat imparted to a body *in vacuo* has ever required the fraction of a gramme to be added to the other scale-pan. But, when gravity is concerned, we cannot add the most minute microscopical molecule without having the equilibrium disturbed.

Gravity alone, of all the imponderables, rises up equal to the burden laid upon it. Its power seems to increase with the amount of matter involved or work to be done. The more required from it, the more it does. You cannot overburden it. An avalanche of rocks or a gossamer thread are equally the playthings of gravity.

For the purpose of these Cantor lectures, the law of gravitation which binds the planets in their courses is of little concern, unless we find that the same law binds the material elements with which we are concerned. The question whether the influence whose law Sir Isaac Newton so clearly propounded resulted from an unknown and ungovernable something, resident and centralised, as it were, within the planets, or whether it was a property of every molecule or group of molecules, was not set at rest until Nevil Maskelyne, the Astronomer-Royal at Greenwich, went to Mount Schiehallien, in Perthshire, in 1774, to calculate the density of the earth.

The mountain of Schiehallien has very steep sides. Mr. Maskelyne suspended plumb-lines from two opposite and nearly vertical sides. Now, if those plumb-lines deviated from what one may call verticality, they would have been caused to deviate by the attraction of the mass of the mountain. Thus Maskelyne examined this—he had an instrument by means of which he could, by observations upon the stars, determine the exact direction that the plumb-line should take, and he found that the strings did not take that direction. Having done that on one vertical side of the mountain, he repeated the experiment on the other side, and found that the deviation there was opposite to that which it was on the first side.* Having determined that these strings no longer followed the vertical, he formed an estimate of how much this mountain attracted the plumb-bob at the end of the string, and so arrived at a conclusion that each particle of matter does attract every other particle. This was the first approximation to an estimate

* The deviation was noted by a zenith-sector, and after making the requisite corrections there was left an attraction which caused the two lines to be drawn together, so including an angle of 12 seconds due to the mountain.

of that which forms a very important element in connection with other experiments. We may here state that in certain regulator-clocks the makers put the single weight in the corner of the case, so that, being removed to the greatest distance, its influence upon the pendulum-bob, similar to that of Schiehallien upon the plumb-bob, may be the least possible.

This, then, established the fact that the power whose law Newton discovered was no gnome resident in some mysterious terrestrial centre, but was a property of every molecule of matter, and could not by any means or contrivance be separated from those molecules. Whether this property be within the molecule, or only in what may be called the atmosphere around the molecule, may be left to those who arrange theories.

(To be continued.)

NOTICES OF BOOKS.

Third Annual Report of the Deputy-Master of the Mint, 1872.

In this official report, with its fourteen appendices, we meet with a variety of important information. We learn, for instance, that the "machinery of the Mint was constructed between the years 1805 and 1816, since which time nearly every appliance of minting in other countries has been gradually changed, while in this country but little advance has been made, and the result is that, although the English Mint is bound by law to coin with much greater accuracy than foreign mints, its machinery is less efficient than that of even the least well-appointed mint in Europe." That such a state of things is not creditable to a country which boasts of being the fruitful mother of mechanical improvement will be readily admitted, and we have not the smallest doubt that such impediments are a "constant source of anxiety" to the Department, and of needless expense to the nation.

The differences of assay reports come very naturally here under notice. We read that "when the reports of the Assayer of the Mint, by whom gold ingots imported for coinage are assayed, do not agree with those of the trade-assayers by which the ingots are accompanied, the former almost invariably indicate the presence of less gold than the latter." It is a fact but too well known to the initiated that large operators in bullion generally press the assayer to give high returns. If he, feeling certain that he is right, declines to "cook" his results, they withdraw from him, their patronage. Thus a class of "high" assayers have sprung up, whose reports very naturally do not agree with those of the Assayers to the Mint.

The Annual Report gives some curious information concerning the coinage of other countries. We learn that in Japan the mint is being placed upon an improved footing, and that large sulphuric acid works, under the direction of an English superintendent, are in course of erection.

The most interesting portion of this pamphlet is naturally the "Memorandum" of Mr. Roberts, the able and energetic Chemist to the Mint. According to this document, 30,334 assays have been made during the year—19,446 of gold, and 10,888 of silver. The amount of "brittle gold," set aside as unfit for working, was 17,000 ozs., whilst, during the year before, it was no less than 40,000 ozs. Mr. Roberts is enabled to state, as the result of his experience, that the "chlorine process" for toughening brittle gold is the most effectual method hitherto devised. The new process of spectroscopic assaying devised by Mr. J. N. Lockyer, F.R.S., has been experimentally tested. Mr. Roberts is of opinion that the use of the spectroscope for quantitative analysis well deserves careful examination. He states that, whilst the existing method—the gold-parting assay—"affords results

which are trustworthy to the 1-10,000th part of the weight of the assay piece, in the examination of a series of gold-copper alloys by means of the spectroscopic differences of composition more minute than the 1-10,000th part can be readily distinguished. By the spectroscopic method, too, the value of the assay piece can be determined in a few methods, whilst an assay by the ordinary method can hardly be completed in less than two hours. Mr. Roberts does not describe the exact method of manipulation, which has not been finally decided upon.

Traces of gold, enough to render their separation remunerative, have been found in the worn-out silver coinage, and in this manner 81.27 ozs. of gold have been recovered from 117,048 ozs. of old crowns and half-crowns. Among the appendices is an interesting, but long, correspondence on the preparation of new trial-plates of gold and silver.

CORRESPONDENCE.

ON BUTTER.

To the Editor of the Chemical News.

SIR,—I cannot agree with Mr. Martin Murphy that the fat globules in milk have no "enveloping tissue or coating." A drop of milk under the microscope—using 1.50th focal length—shows the field full of capsules containing fat, with a small proportion of free oil globules, some being very minute. When treated with acetic acid the globules coalesce; but chloroform does not dissolve the fat in the capsules without agitation, whilst the free oil globules instantly vanish into that liquid.—I am, &c.,

CHARLES A. CAMERON.

Dublin, July 29, 1873.

ON BUTTER.

To the Editor of the Chemical News.

SIR,—In addition to the methods for the detection of the adulterants in butter, which have of late appeared in the CHEMICAL NEWS, would specific gravity not be of importance if carefully applied? Supposing a portion of butter was taken, melted, raised to a temperature sufficient to melt the bodies resulting from a mixture of pure butter with an adulterant—so that their specific gravities could be compared at the same temperature—and its specific gravity taken.

Make mixtures—say with 1 to 10 per cent of the adulterant and pure butter; get these to the same temperature ascertain their specific gravities, compare with pure butter, and note the difference.

Specific gravity is very useful in many such examinations. If any one has tried experiments of that nature on butter, and if it would not be too much to ask, I would, through curiosity, like to know a little of the results.—I am, &c.,

GEORGE ALSTON.

London, July 22, 1873.

THE BUTTER CONTROVERSY.

To the Editor of the Chemical News.

SIR,—With all due deference to Dr. Campbell Brown, as I was so much longer in the field on this subject than Dr. Ballard, it would have been but courteous if he had begun at the beginning; as Dr. Ballard himself in his paper (see CHEMICAL NEWS, vol. iv., p. 283) alluding to my communication (vol. iv., p. 230), as also in vol. iv., p. 309, admits that I was about the first to publish anything like a satisfactory test on the subject; and in that very paper (vol. iv., p. 309) I called attention to be microscopic characteristics of butter and lard, after

which followed several other letters between us on different kinds of fats. *Litera scripta manet*. I have seen nothing yet to disturb my views, or throw any new light on the matter; but I do not like my labours to be altogether ignored, notwithstanding it is twelve years ago since my communications were made in the CHEMICAL NEWS.—I am, &c.,

JOHN HORSLEY, F.C.S.,
Analyst to the County of Gloucester.

Cheltenham, July 29, 1873.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Under this heading will be found an encyclopaedic list of chemical papers published abroad during the past week, with abstracts of all susceptible of advantageous abridgment. The two half-yearly volumes of the CHEMICAL NEWS, with their copious indices, will, therefore, be equivalent to an English edition of the "Jahresberichte."

NOTE. All degrees of temperature are Centigrade, unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances de l'Académie des Sciences, July 7, 1873.

Heat of Combination in reference to the Solid State; a New Thermic Expression of Reactions.—M. Berthelot.—A thermo-chemical paper. The author gives an account of the heat of solution of monobasic salts, including formiates, acetates, benzoates, picrates, nitrates, chlorides, bromides, iodides, cyanides, &c.; of the bibasic salts, sulphates, oxalates, tartrates, and carbonates. He then examines the relations between the heats of solution, the formation of crystalline hydrates, of acid and double salts, the reciprocal displacement of acids in salts and saline double decompositions.

New Isomer of Valerianic Acid.—C. Friedel and R. D. Silva.—The authors have in a former communication described pinacolic alcohol derived from pinacoline by hydrogenation, and have announced that the oxidation of this alcohol reproduces pinacoline, and that the latter, in turn oxidised by bichromate of potassa and sulphuric acid, yields an acid isomeric with the valerianic. They have since continued the study of this acid, which they have named *pinalic*. They observe that it has a considerable resemblance to the trimethylacetic acid of Bouletrow.

Mode of Decomposition of Explosive Bodies, Compared with the Phenomena of Supersaturation.—P. Champion and H. Pellet.—The name of explosives is given to compounds or mixtures which under various circumstances liberate a volume of gas whose rapid formation causes an explosion more or less powerful. In certain cases, as in the powders of which common gunpowder is the type, the explosion is derived from combinations between the elements which compose. In others, as in the substances of indefinite composition—such as the ethers of the mono-atomic and poly-atomic alcohols, the fulminates, the compounds of nitrogen with several non-metallic elements, &c.—the explosion results from the violent separation of the elements. This definition appears limited to a restricted number of phenomena, whence the authors have concluded that, in order respectively to distinguish bodies with regard to their rapid decomposition, a classification into stable and unstable would be more appropriate to this kind of phenomena. From this point of view we might designate as unstable the bodies or compounds in which the equilibrium, if broken in one point and under given conditions, determines the immediate decomposition of the whole mass with a rapidity and an evolution of heat depending

on the nature of the body and on the circumstances to which it is exposed. A great number of unstable bodies can manifest their change of state in different manners, either by a rapid decomposition giving rise to a true detonation, or by the more gradual separation of the component elements. Dynamite and gun-cotton, which can be decomposed by ignition, flame, or a violent shock (such as that of a detonator), present a striking example of these facts. The name which the authors propose might also be extended to modifications of the physical state. It is now only one step to compare the unstable state of equilibrium of explosive compounds with that of supersaturated solutions, as Gernez has done. The authors have sought to establish precise analogies between the phenomena which accompany the different modes of action of supersaturated solutions and of unstable compounds, among which they have selected dynamite, on account of the facility with which it undergoes decompositions of different grades. Supersaturated solutions may be considered as unstable compounds of water and of a hydrated salt, in which dissolution is effected by contact of a crystal of the same salt or its isomorphs. This crystal represents the detonating primer which effects the rapid decomposition of nitro-glycerine. In fact, whilst a few decigrammes of fulminate of mercury induce the explosion of dynamite, iodide of nitrogen, sufficient in quantity to be mechanically equivalent to the fulminate, is unable to explode the dynamite. In presence of a suitable charge of fulminate of mercury, dynamite explodes, whatever is its quantity and whatever may be the form of the containing vessel. A sufficient weight of sulphate of soda, at ordinary temperatures, determines the crystallisation of supersaturated sulphate even in those cases of "desensibilisation" which will be examined below. The diameter of the tubes containing the sulphate of soda, and the shape of the recipients, are without influence on the speed of crystallisation. A supersaturated solution, enclosed in a tube with several elbows and having a length of 48 centimetres, has crystallised in the same time as a similar solution placed in a straight tube of the same length. If the primer is insufficient, the dynamite undergoes merely a partial decomposition, and in certain cases does not ignite. On its part, supersaturated sulphate of soda presents different crystallisations, resembling the modes of action of the primer. Supersaturated solutions crystallising under the influence of particles of sulphate of soda contained in the air, yield long crystalline needles. If, on the contrary, voluminous crystals of sulphate of soda are introduced into the solution, a confused crystallisation prevails, and the crystals appear partly broken. The addition of an inert body in excess (silica, &c.) to nitro-glycerine completely modifies its sensibility, and transforms it into a compound which even resists energetic shocks. A corresponding result is obtained with supersaturated solutions. To 50 c.c. of a supersaturated solution of sulphate of soda were added—

	Crystallisation, caused by Atmospheric Dust, is Effected in— Seconds.
Water, 2 grms.	37
Glycerine, 2 grms.	41
Chloride of sodium, 2 grms.	40
Nitrate of potassa, 2 grms.	51
Carbonate of soda, 2 grms.	62
Sulphate of ammonia, 2 grms.	64
Sulphate of soda, 46 grms., in water, 72 grms.	114
Replacing the glycerine with syrup of sugar, 100 grms.; water, 50 (?)	177
Glycerine at 28°, 12.5 c.c.; super- saturated sulphate of soda, 25	360
Water, 72 grms.; sulphate of soda, 46 grms., saturated with car- bonate of soda	900

If, to 25 c.c. of a solution of supersaturated sulphate of soda, we add 12.5 c.c. of a solution of nitrate of potassa

saturated in the cold, the mixture can be left exposed to atmospheric dust without effect. Crystallisation can only be induced by the direct introduction of sulphate of soda in crystals of an appreciable bulk. The addition of foreign bodies acts, therefore, in a similar manner both with nitro-glycerine and with supersaturated solutions, which results from the separation of the molecules, and the difficulty which each experiences in undergoing the influence of the neighbouring molecule. As to the action of temperature, by reason of the very nature of the phenomena between which it is sought to establish analogies, we comprehend that their action must be inverse in the two cases, in order to give place to comparable phenomena. At low temperatures the explosive power of dynamite, and of explosives in general, decreases notably, whilst, in the same conditions, the instability of supersaturated solutions augments rapidly. A charge of 0.2 c.c. of fulminate of mercury is without action upon dynamite at 75° cold. A supersaturated solution of sulphate of soda, placed in a tube, crystallised in 39 seconds at a temperature of 15° to 16°; whilst, at 8°, the crystallisation was completely effected in 19 seconds with the same depth of liquid. A similar inversion of results was again produced on introducing into a supersaturated solution a pulverulent body, and if, reciprocally, the silica, which serves as an absorbent for nitro-glycerine, is replaced by any solvent. Wood-spirit, added to nitro-glycerine in the proportion of $\frac{1}{4}$ to $\frac{1}{2}$ per cent, prevents it from exploding, but, in this case, the very nature of the body is seriously modified. On the other hand, the presence of a sufficient quantity of an absorbent, like silica, prevents supersaturation. In these experiments with dynamite, the nitro-glycerine may be replaced with any analogous compound, such as nitro-glycol, nitro-erythrite, &c. The foregoing series of facts appear to the authors sufficient to establish a direct relation between the phenomena of supersaturation and those presented by explosive bodies.

Transformation of Succinic Acid into Maleic Acid.—M. E. Bourgeon.—Maleic acid has been converted into succinic acid in certain phases of fermentation, and the same transformation is effected in an analogous manner and more regularly under the influence of hydrogen. The author has observed an inverse reaction whilst examining the effects of heat upon the succinate of silver; part of this salt is split up into silver and maleic acid, according to the following equation:— $C_8H_4Ag_2O_8 = Ag_2 + C_8H_4O_8$.

Action of Chloride of Benzyl upon Naphthylamin.—Ch. Froté and E. Tommasi.—On causing chloride of benzyl to react upon naphthylamin in heat, in presence of a small quantity of zinc-powder, the authors obtained a compound isomeric with cresyl-naphthylamin, but differing from the latter in the substitution of an equivalent of benzyl for an equivalent of cresyl. Benzyl-naphthylamine melts at 66° to 67°, whilst its isomer melts at 79°. Its composition is—

Carbon	87.59
Hydrogen	7.20
Nitrogen	5.34

Experimental Researches on the Action of Nitrous Oxide Gas.—F. Jolyet and T. Blanche.—A physiological paper. The authors conclude, from their experiments, that pure protoxide of nitrogen cannot maintain the respiration either of plants or animals. Seeds refused to germinate in an atmosphere of this gas.

Crystalline Forms of the Lanarkite of Scotland.—All. Schrauff.—The crystals measured by the author contain no more carbonic acid than those analysed by Pisani.

New Clinical Researches on the Localisation, in the Anterior Cerebral Lobes, of the Action by which the Brain Concurs in the Psycho-Physiological Faculty of Speech.—M. Bouilland.—The author distinguishes two centres in these lobes—one having reference to the act of pronunciation the other to the words themselves.

Optical Telegraphic System Realised, during the Siege of Paris, by a Commission Appointed by the Governor.—M. Laussedat.—This gives the contents of a sealed packet deposited with the Academy in April, 1872. (An Italian journal has recently described a similar system to that experimented with during the siege). The principle of the apparatus is this—Conceive two telescopes, *ab* and *a'b'*, directed towards each other so that their optic axes coincide. Behind the telescope *a'b'*, and near its eye-piece is placed a light, *e.g.*, the flame of a candle. If the distance is not too great, and the observer looks through the telescope *ab*, he will perceive the image of the flame as a bright point. If the distance between the telescope is increased, it will be necessary to increase the intensity of the luminous source, or the aperture to the objectives. The brightness of the image, as seen through *ab*, depends on the elements now mentioned (intensity of source, distance, aperture) and on the state of the atmosphere. A screen is inserted and withdrawn at proper intervals, being worked with a Morse instrument. The signals are rendered invisible to all but the operators. Such apparatus was furnished to some of the Paris forts; the maximum distance was that between Valerien and Fort de Nogent, 20 kilometres. A balloon left Paris in December, during the siege, with apparatus for connecting Paris thus with the provinces; and M. Lissajous gives a report of the attempts made, in some cases with success. The system was successfully used by day (and with sunlight) in General Chanzy's army.

Constitution of the Sun and the Theory of Spots.—M. Vicaire.—Reserved.

The Cyclones of the Sun Compared with those of our Atmosphere.—M. Tarry.—M. Faye, instituting a parallelism between solar and terrestrial cyclones, asserts a movement of rotation from above downwards. The Italian spectroscopists deny this descending movement as regards solar cyclones. The present writer asserts that, in the terrestrial, the rotatory aspiration is from below upwards. A whirlwind sucks up trees, roofs of houses, the water from ponds, &c. A cyclone passing over Sahara raises great quantities of sand, which afterwards fall, frequently, on the Mediterranean and in the south of Europe. Further, if the air were sucked down, it would become hotter as it descended, and the vapour it contained would not be precipitated in form of rain; now the passage of cyclones is always marked by heavy rains. This error of M. Faye's does not, in the author's opinion, vitiate his theory, which M. Tarry only wishes to put on a firmer basis. The cyclones in the sun suck up first hydrogen, then denser matters. The metallic vapours are condensed in the colder regions, and fall back in liquid drops to the interior. All the facts urged by the spectroscopists against M. Faye's theory become arguments in its favour, if we only modify the theory as stated.

Some Details of the Earthquake of June 29.—M. Fonvielle.—The centre of the catastrophe was in the Marino valley, in the district of Vittorio. Two days before, the lake of Santa Croce suddenly fell several feet, and rumblings were heard in a village on the north side on the 28th. Some streams which enter and leave the lake became muddy after the earthquake, one taking a red colour, as of blood. The churches contained a good many people, and several were killed by falling stones. The telegraph lines were broken at various points, showing great violence of oscillation. The earthquake was felt in Italy, in Germany, in the Tyrol, and even as far as Munich. A very violent whirlwind appeared at Vienna at the same time, carrying off the captive balloon to a distance of 30 kilometres. Other details are given.

Revue Scientifique de la France et de l'Etranger,
July 12, 1873.

This number contains a lecture by Prof. C. Bernard, on the "Formation of Sugar in the Liver and the Blood."

Les Mondes, Revue Hebdomadaire des Sciences, par L'Abbé Moigno, Tome xxxi., No. 11, July 10, 1873.

New Electric Pile.—M. Zaliwski.—The author takes two porous cells, one of which fits very loosely in the other. Into the inner cell, containing the carbon, he pours nitric acid; into the other, sulphuric acid; and into the outside non-porous containing-vessel, fitted up with a cylinder of sheet-zinc, a saturated solution of sal-ammoniac. The arrangement of the liquids is, therefore, nitric acid, sulphuric acid, solution of sal-ammoniac.

Artificial Butter.—Ordinary fats are composed of three substances—Stearin, which is as hard as wax; margarin, of the consistence of butter; and olein, a liquid. When these three are separated by chemical means, the first may be employed for candles, the second for butter, and the third for lubricating machinery. A company is at present operating upon beef-fat, at No. 45, Newark Street, New York. In taste and in appearance the butter thus made is exactly similar to the best butter made from cows'-milk. Prof. Parof, the inventor, hopes to drive genuine butter completely out of the market. (Margarin may have the consistence, but can never possess the flavour, of butter, which depends upon small quantities of butyric, capric, and caproic acids; very similar operations are being conducted in England, the raw material being the fat of horses obtained from the knackers).

Albumen Obtained from Milk.—M. Schwalbe has found that by adding one drop of the oil of mustard to 20 grms. of cows' milk, the casein is transformed into albumen. If this discovery is confirmed, it will be of great importance in the art of calico-printing.

Natural Red Silk.—M. Ruimet des Taillis, writing in the *Chronique de la Société d'Acclimatation*, states that, by feeding silkworms on vine leaves, he has obtained cocoons of a magnificent red, and, by employing lettuce, others of a deep emerald-green. M. Delidon de Saint Gilles, of Vendée, has obtained silk of a beautiful yellow, other samples of a fine green, and others again of a violet, by feeding the silkworms on lettuce or on white nettle. He points out that the silkworms must be fed on mulberry leaves when young, and supplied with the vine, lettuce, or nettle leaves during the last twenty days of the larval stage of their life.

No. 12, July 17, 1873.

Cure for the Bites of Gnats.—Claude Collas.—The remedy is the application of sinapised paper.

Means of Accelerating the Germination of Plants.—Dr. Grouven.—The seeds were steeped in an aqueous solution of nitrate of potassa, containing 5 per cent of the dry salt.

On Silica.—Dr. E. Robert.—Observations and speculations on the formation and transformation of siliceous minerals.

Properties and Uses of Kieserite.—A paper, extracted from the *Scientific American*, on the commercial applications of the Stassfurt salts.

Ozokerit Candles.—Ozokerit is found in beds in the sandstone of Slanik, in Moldavia, in the neighbourhood of mines of coal and of rock-salt; it has also been discovered in the Carpathians. The material in its crude state is brown, greenish, or yellow; it is translucent at the angles, and its fracture is resinous. It is naturally brittle, but when softened can be kneaded like wax. It blackens on exposure to the air. It becomes negatively electric on friction, and exhales then the aromatic odour of a hydrocarbon. It melts at the low temperature of 66°. Its illuminating power is such that 754 ozokerit candles give a light equal to 891 of paraffin, or 1150 of wax.

Explosive Antimony.—If a slip of copper is attached to the negative pole of a battery, and a slip of platinum to the positive, and if these two electrodes are plunged into a solution of chloride of antimony, the latter meta

is deposited upon the copper in a brilliant layer. After having been well washed, the antimony, which is very brittle, is detached. It detonates violently, with evolution of light and heat, if rubbed in a mortar or struck with a hammer.

Preparation of Stuffs against Moths.—Dr. Reimann recommends to steep the stuffs for twelve hours in the following solution:—Dissolve in hot water 4.534 kilos. of alum and 9.68 kilos. of acetate of lead. Let the sulphate of lead settle; draw off the clear liquid, and add 8.18 litres of water in which a little isinglass has been dissolved. After steeping, the goods are dried and finished in the ordinary manner.

Mineral Caoutchouc.—This remarkable substance, which is now imported from Australia, is found at Coorong in thin layers. On analysis, it appears to have a generic relation with petroleum.

Alcohol from Mosses and Lichens.—This manufacture has spread from Sweden to Russia, and is now carried on upon a large scale. The produce is considered of good quality, and is obtained to very great advantage.

No. 13, July 24, 1873.

No. 6. 1873.

Application of Aniline to Photography.—M. Tronquoy.—A solution is prepared containing sulphuric acid and some grammes of bichromate of potassa. A sheet of paper is saturated with this liquid in the dark; it is allowed to dry, and then placed under the design in a frame. The design is reproduced on the paper in a straw-colour. It is taken out, and exposed in a box to the vapours of aniline. By its action the bichromate and chromic acid not reduced take a colour varying from green to blue-violet. It is washed in abundance of water.

Photo-Chemical Researches on the Use of Gaseous Developing Agents, and on the Influence of the Molecular State as regards Sensibilisation.—M. Merget.—The gaseous bodies experimented upon were hydrogen, sulphide of hydrogen, and the vapours of iodine and mercury.

Dark Chamber called "Composition Chamber," making it possible to obtain a Landscape from Separate Positions, which are then Combined in Single Proof.—M. Desflubé.—An account of an ingenious

contrivance which may probably prove of great importance in landscape photography.

Modifications of the New Carbon Processes called "Contact-Mariotype" and "Pressure-Mariotype."—A. Marion.—The new procedure is a combination substituting alum and blended papers for the fatty inks, without the intervention of light.

MISCELLANEOUS.

British Association for the Advancement of Science.—In consequence of the illness of Dr. Joule he will be unable to preside over the meeting at Bradford, which commences on the 17th of September, and the Council have therefore appointed Dr. A. W. Williamson, F.R.S., to the office of President for the year. The following shows the Vice-Presidents and Officers of the Association, as well as of the various sections and departments:—Vice-Presidents elect—the Earl of Rosse, F.R.S., F.R.A.S.; Lord Houghton, D.C.L., F.R.S.; Mr. W. E. Forster, M.P.; the Mayor of Bradford; Mr. J. P. Gasiot, D.C.L., F.R.S.; Prof. Phillips, D.C.L., F.R.S.; Mr. John Hawkshaw, F.R.S., F.G.S. Local Secretaries for the meeting at Bradford—the Rev. J. R. Campbell, D.D.; Mr. R. Goddard; Mr. Piele Thompson. Local Treasurer for the meeting at Bradford—Mr. Alfred Harris, jun. General Secretaries—Captain Douglas Galton, C.B., R.E., F.R.S., F.G.S.; Dr. Michael Foster, F.R.S., Trinity College, Cambridge. Assistant General Secretary—Mr. George Griffiths, M.A. General Treasurer—William Spottiswoode, M.A., LL.D., F.R.S., F.R.G.S. Auditors—Mr. John Ball, F.R.S.; Mr. J. Gwyn Jeffreys, F.R.S.; Colonel Lane Fox, F.G.S. The sections are the following:—A. Mathematical and Physical Science.—President—Prof. Henry J. Stephen Smith, LL.D., F.R.S. Vice-Presidents—Prof. Balfour Stuart and Prof. Henrich. Secretaries—Prof. W. K. Clifford, M.A.; J. W. L. Glaisher; Prof. A. S. Herschell; and Prof. Forbes. B. Chemical Science.—President—Dr. W. J. Russell, F.R.S. Vice-Presidents—Prof. Roscoe and I. Lowthian Bell. Secretaries—W. Chandler Roberts, F.C.S.; Dr. Armstrong; and Prof. Thorpe. C. Geology.—President—Prof. Phillips, D.C.L. Vice-President—W. Penckelly. Secretaries—Louis C. Miall; William Topley, F.G.S.; R. Tiddeman. D. Biology.—Vice-Presidents—Dr. Beddoe and Prof. Rutherford, M.D. Department of Zoology and

Botany. Secretaries—Prof. Thiselton-Dyer and Prof. Lawson. Department of Anatomy and Physiology.—Secretaries—E. Ray Lankester and Dr. Pye-Smith. Department of Anthropology.—Secretaries—F. W. Rudler, F.G.S., and J. H. Lamprey. E. Geography.—President—Sir Rutherford Alcock. Vice-Presidents—Major-Gen. Sir Henry Rawlinson and John Ball. Secretaries—H. W. Bates, F.L.S., F.R.G.S.; Keith Johnston, F.R.G.S.; and Clements R. Markham, C.B. F. Economic Science and Statistics.—President—Mr. W. E. Forster, M.P. Vice-Presidents—Dr. Farr; Lord Houghton, D.C.L.; E. Baines, M.P. Secretary—J. G. Fitch, M.A. G. Mechanical Science.—President—W. Froude, LL.D. Vice-President—A. Bessemer. Secretaries—H. M. Brunel; J. N. Shoolbred; H. Bauerman.

Quekett Microscopical Club.—The eighth annual general meeting was held on Friday evening last, July 25, at University College, Gower Street; Dr. Braithwaite, F.L.S., F.R.M.S., President, in the chair. The report of the Committee for the past year was read, and testified to the continued prosperity of the Club, which now numbers 570 members. The President delivered the annual address, in the course of which he noticed the progress of microscopical investigation in Botany and Zoology. The ballot then took place for the election of officers. Dr. Braithwaite was re-elected President; Dr. Matthews, Messrs. B. T. Lowne, T. W. Burr, and C. F. White, Vice-Presidents; and Messrs. Bywater, Crisp, Hailes, Hind, Waller, and T. C. White, were elected to fill the six vacancies on the Committee, and Mr. J. E. Ingpen succeeded Mr. T. C. White, who retires from the office of Honorary Secretary, owing to the increase of his professional duties, after four years of unremitting and valuable service. The proceedings terminated with the usual *conversazione*.

PATENTS.

ABRIDGMENTS OF PROVISIONAL AND COMPLETE SPECIFICATIONS.

An improved method of carbonising clay, plaster, chalk, porous stone, and other like porous materials. George Hand Smith, 8, Southampton Buildings, London. December 24, 1872.—No. 3915. My invention relates to a novel treatment of porous materials and articles or objects made thereof, whereby they are converted into materials possessing properties altogether different to those peculiar to them in their normal condition. My said invention consists in a process of treating such absorbent materials by first causing them to absorb carbon from a liquid containing the same, and then expelling the volatile portions of the carbon; and the said invention is applicable to the treatment of all substances capable of absorbing and retaining the carbon.

Improvements in utilising waste products of chemical and other works, in order to render the same applicable for building and structural purposes. William McAdam, Glasgow, Lanark, N.B. December 27, 1872.—No. 3924. The feature of novelty which constitutes this invention is the utilising of the waste products of soda-ash works, alkali, soap, iron, and other chemical works, and converting the same into bricks or blocks of solid material suitable for building and other structural purposes.

Improvements in distilling, evaporating, or concentrating saccharine and other solutions or liquids. David Crawford Miller, bleacher, Larkhall, Lanark, N.B. December 27, 1872.—No. 3926. The feature of novelty constituting this invention is the causing air or vapours or gases to pass into and through the solutions or liquids to be distilled, evaporated, or concentrated.

Improvements in and apparatus for extinguishing fire. William Lattimer, manufacturer, Holme Head, near Carlisle, Cumberland. December 27, 1872.—No. 3927. The invention consists in storing or preserving the chemical ingredients which, when combined, produce carbonic acid gas or other vapours for extinguishing fire, in two or more separate vessels or compartments provided with connecting pipes, instead of combining these ingredients as now customary in the case of the "fire extinguisher." The ingredients, being kept separate until they flow from their separate vessels and unite in the delivery pipe, produce the maximum effect.

Improvements in treating liquids to be burned for illuminating purposes. Benjamin White, chemist, and Patrick Thoms Hendry, commission merchant, Glasgow, Lanark, N.B. (A communication from Joseph Hale, jun., Cincinnati, United States). December 27, 1872.—No. 3930. The invention consists in taking naphtha of a specific gravity of about 60° or 65° Baumé, and mixing every 40 gallons of it with 4 lbs. pulverised alum, 5 ozs. camphor, 2 lbs. starch (by preference that obtained from potatoes), and 4 ozs. oil of sassafras. The mixture is kept for two or three days, and is well stirred at intervals, after which the liquid part is separated by filtration, and is then ready for use.

NEW EDITION OF MITCHELL'S ASSAYING.

Just published, in 8vo., with 199 Woodcuts, price 31s. 6d.

A Manual of Practical Assaying. By JOHN MITCHELL, F.C.S. Fourth Edition, in which are incorporated all the recent valuable improvements in Assaying made in this country and abroad; including Volumetric and Colorimetric Assays, and the Blowpipe Assays, Edited, and for the most part re-written, by WILLIAM CROOKES, F.R.S., &c.

"The work, as it now stands, may safely be taken as a guide by buyers of ores, and by all persons engaged in the industry of chemical manufacture."

Mining Journal.

London: LONGMANS, GREEN, and CO., Paternoster Row.

Chemical Technology, or Chemistry in its Applications to the Arts and Manufactures. By THOMAS RICHARDSON and HENRY WATTS. Second Edition, illustrated with numerous Wood Engravings.

THE CHEMICAL NEWS.

VOL. XXVIII. No. 715.

ON THE QUANTITATIVE ESTIMATION OF CHROMIUM, AND THE SEPARATION OF CHROMIUM FROM URANIUM.*

By WOLCOTT GIBBS, M.D.

THE quantitative separation of chromium from uranium appears not to have specially attracted the attention of chemists. No method is given either by Rose or by Fresenius. The two metals rarely, if ever, occur associated in the mineral kingdom, and the only definite artificially prepared compound which I have been able to find noticed is the uranic chromate described by Jahn, who does not appear to have analysed the salt, though Berzelius—judging probably from the mode of formation—attributes to it a formula which we should now write $U_2O_2.Cr_2O_3$. Berzelius also states that neutral potassic chromate gives, with uranic chloride, a yellowish brown precipitate, which contains both oxides of uranium, as well as chromic oxide and acid. This compound also appears not to have been analysed.

As the method of separating the two metals to which I finally arrived involves the presence of the chromium as chromic acid, I began my investigation by examining the commonly received methods of estimating this substance.

Rose strongly recommends the method of Berzelius, which consists in precipitating the chromic acid by mercurous nitrate, and washing with a dilute solution of the same salt. The precipitated chromate is voluminous, and has a brown-red colour when the precipitation takes place in the cold. I find that a better result is obtained by precipitating at a boiling heat, when the mercurous chromate almost immediately becomes highly crystalline, its colour changing to a bright scarlet. It may then be washed with the greatest ease, and ignited in the usual manner. It is absolutely necessary, in applying this method, that the mercurous nitrate used should be perfectly free from nitrous acid. Want of attention to this point led me formerly into an error, which I desire to correct in this place. I have stated in a former paper† that hot solutions must not be employed, on account of the reduction of chromic acid by mercurous nitrate. This reduction is not due to the temperature, but to the presence of a small quantity of nitrous acid in the mercurous nitrate employed. It is easy to avoid this source of error by dissolving the mercury in nitric acid in an open vessel, and crystallising the nitrate two or three times, using for solution dilute nitric acid which has been perfectly freed from nitrous acid by a current of air or carbonic dioxide.

To test the method thoroughly, the following analyses were made with pure potassic dichromate:—

I. Salt precipitated at a boiling heat by mercurous nitrate, and washed with hot water alone.

1. 0.6003 gr. gave 0.3030 gr. $Cr_2O_3 = 50.47$ p.c. Cr_2O_7 .
2. 0.4741 " 0.2407 " = 50.77 "

The formula $K_2Cr_2O_7$ requires 51.73 per cent if we take $Cr = 52.2$.

II. Salt precipitated cold by mercurous nitrate, and washed with cold water only.

3. 0.2641 gr. gave 0.1344 gr. $Cr_2O_3 = 50.89$ p.c. Cr_2O_7 .
4. 0.5098 " 0.2607 " = 51.13 "

III. Salt precipitated cold, then boiled, and washed with boiling water only.

5. 0.4957 gr. gave 0.2503 gr. $Cr_2O_3 = 50.49$ p.c. Cr_2O_7 .
6. 0.6393 " 0.3288 " = 51.43 "

IV. Salt precipitated cold, then boiled, and washed with hot water containing mercurous nitrate.

7. 0.4951 gr. gave 0.2558 gr. $Cr_2O_3 = 51.67$.
8. 0.3639 " 0.1881 " = 51.69.

In these last analyses the error of the mean is only 0.04 per cent. We arrive, however, more quickly at our object when we precipitate at once at the boiling-point, and then wash with a hot dilute solution of the nitrate.

In several works on analytical chemistry it is recommended to precipitate chromic acid from its solutions by plumbic acetate, and to weigh the resulting chromate of lead. In repeated trials I have never been able by any artifice whatever to prevent the precipitated plumbic chromate from passing more or less through the filter so as to render the filtrate turbid.

Precipitation of chromic acid by a baric salt was next examined. Potassic dichromate was precipitated by baric acetate, with the following variations:—

I. Salt precipitated by baric acetate at a boiling heat, and washed with water only; chromate weighed upon a porous earthenware filter.

1. 0.4617 gr. gave 0.7894 gr. $BaCrO_4 = 51.41$ per cent.
2. 0.4685 " 0.8022 " = 51.52 "

II. Salt precipitated by baric acetate at a boiling heat, alcohol added, and the precipitate washed with a hot mixture of 3 parts of water and 1 part of alcohol of 90 per cent, and ignited.

3. 0.3802 gr. gave 0.6546 gr. $BaCrO_4 = 51.78$ per cent.
4. 0.5282 " 0.9069 " = 51.66 "

III. Salt precipitated by baric acetate without alcohol. Solution after precipitation evaporated to dryness upon a water-bath, then washed with hot water and ignited.

5. 0.5366 gr. gave 0.9229 gr. $BaCrO_4 = 51.75$ per cent.
6. 0.5355 " 0.9204 " = 51.71 "

In the last analysis alcohol was added to the wash-water. From this it appears that very accurate results may be obtained by precipitation with baric acetate at a boiling heat, adding a small quantity of strong alcohol to the liquid, washing with water containing alcohol, and igniting. The wash-water need not contain more than 1-12th of its volume of alcohol. The precipitated chromate must, before filtering, be allowed to settle completely, leaving the supernatant liquid perfectly clear. The filtrate never becomes turbid, even after all the soluble salts are washed out. Finally, it is not necessary to weigh the baric chromate upon a weighed filter. A very small quantity of the chromic acid is always reduced by the carbon of the filter in igniting, but the loss of weight is inappreciable. This method is much shorter than that which is usually employed, as the filtration and washing may be executed almost immediately after precipitation.

The conditions necessary for the complete precipitation of chromic acid, either as mercurous or baric chromate, having been thus carefully reviewed, I next proceeded to attempt the quantitative separation of uranium and chromium. In a first series of experiments, weighed quantities of potassic dichromate were mixed with much larger, but undetermined, quantities of uranic nitrate. The chromic acid was then precipitated by mercurous nitrate from the boiling solutions. In this manner the following results were obtained:—

Gr.	Gr.
1. 0.4120 $K_2Cr_2O_7$	gave 0.2130 $Cr_2O_3 = 51.74$ p.c. Cr_2O_7 .
2. 0.3292 " "	" 0.1702 " = 51.70 "
3. 0.4543 " "	" 0.2353 " = 51.77 "

The mean of these analyses is 51.73 per cent, which is precisely the percentage required by the formula $K_2Cr_2O_7$ ($Cr = 52.2$).

These analyses show that mercurous nitrate gives very accurate results. The employment of this salt in separating chromium from uranium is indicated only in those cases in which the chromium exists as chromic acid, in

* From the *American Journal of Science and Arts*, vol. v., Feb., 1873.
† *Am. Journ. Sci.* [11.], vol. xxxix., p. 59.

which relatively small quantities of chlorine or sulphuric acid are present, and in which no other acid is present which, like phosphoric acid, gives an insoluble mercurous salt not completely volatilised by ignition. In the presence of chlorine, sulphuric acid, &c., the following process may be very advantageously employed. The solution is to be boiled for a few minutes with a small excess of sodic hydrate, the precipitate of sodic uranate filtered off and washed with hot water containing a little sodic hydrate until the washings no longer give any turbidity, with a solution of mercurous nitrate. The sodic uranate in the filter is then to be dissolved in chlorhydric acid, and the uranium determined in the usual manner. The filtrate contains all the chromium as CrO_4Na_2 . After adding chlorhydric acid in excess, the chromic acid may be most conveniently reduced to chromic oxide by adding a solution of potassic or sodic nitrite and boiling for a few minutes, after which the oxide may be precipitated by ammonia in the usual manner. An alkaline nitrite is a better reducing agent than alcohol, as the chromic oxide may be precipitated immediately after the reduction.

It remains to consider the case in which chromic and uranic oxides occur together in solution. A solution of sodic hydrate in small excess is to be added, and the whole heated to boiling. To the hot liquid bromine-water is to be added. Chromic oxide is almost instantly oxidised to chromic acid, which remains in solution as CrO_4Na_2 , while uranate of soda with a small percentage of uranic chromate remains undissolved. After washing with hot water containing a little sodic hydrate, the precipitate, which has a deep orange colour, is to be dissolved in hot nitric acid, the solution boiled for a few minutes, to expel any traces of nitrous acid, mercurous nitrate added, and the whole allowed to stand until the small quantity of mercurous chromate has settled. This, after washing, may be ignited in the same crucible with the chromic oxide obtained as above from the sodic chromate in the filtrate. The filtrate is free from uranium. Repeated attempts to determine uranium by precipitation with sodic phosphate, and final weighing as uranic pyrophosphate, have led as yet to no satisfactory results. It is, however, worth noting that the gelatinous phosphate becomes pulverulent, and easily washed by simple evaporation to dryness.

THE MANIPULATION OF HYDRIC SULPHIDE.*

By JOSIAH P. COOKE, Jun.

THE manipulation of hydric sulphide in a large laboratory has always been a difficult problem, and the inconveniences arising from the use of this reagent in the state of gas are so great that, when a class of forty or fifty students are working with it at once, the nuisance becomes almost unbearable. When dissolved in water, however, this reagent gives as little trouble or annoyance as any other; but, as ordinarily prepared, the solution is so weak that the substance under examination is deluged with water before the required excess of the reagent has been added. This objection can be wholly overcome by dissolving the gas under pressure, and drawing off the solution from a syphon like soda-water, and in any laboratory where water is supplied under pressure such a super-saturated solution can be very readily prepared with a very simple apparatus, which may be mounted in the following manner:—

We use for the purpose the common green glass bottles in which acids are usually sold by the druggists, only taking care to select strong bottles with a well rounded neck about $1\frac{1}{2}$ inches in diameter. Let us designate by A, B, and C three 2-quart bottles of this description, and by D a similar, but larger, bottle, having a capacity of 2 gallons. In A the gas is generated from ferrous sulphide, water, and sulphuric acid, in the ordinary way.

* Communicated by the Author.

We pass the gas from A, first through a wash-bottle filled with moistened sponge, and then through the distilled water with which the bottles B and C are about three-fourths filled, the gas bubbling up as usual from glass tubes leading to the bottom of each bottle, and the excess not absorbed by the water passing forward to the large bottle, C, which serves as a gasometer. All these bottles are fitted as tightly as possible with rubber stoppers, through which pass the stout glass tubes that conduct the gas. Through the stopper of D pass three such tubes: the first, which brings the unabsorbed gas from C, opens at the top of the bottle; the second is connected by a rubber hose with a water faucet, and reaches to the bottom of the bottle; the third serves simply as a vent. The bottles B and C are fitted each with two tubes, one to deliver the gas at the bottom of the bottle, and the second, opening from the top, to conduct away the excess. The gas generator, A, requires only an exit tube; and, lastly, the wash-bottle is fitted in the ordinary way, save only that we pack it with well-washed sponge, by which the gas is more effectually purified than when it bubbles through a liquid. We use glass tubes of about 3-16ths of an inch bore, and rubber hose of the same calibre, but very stout and made of pure vulcanised rubber. The rubber stoppers are cut from what we call *stopper cord*, which, as well as the hose, is made by the Boston Belting Company. In mounting the apparatus, we interpose 2 or 3 feet of hose between the several parts, so as to have sufficient freedom of motion to enable us to shake up the water with the gas in the bottles B and C. Over the ends of the tubes from each of the bottles B and C we stretch permanently two rubber connectors, cut from the hose just described, and depend wholly on *pressure-taps*, acting on these connectors, for closing the bottles. While charging the water with gas, the connectors are united to the hose by short lengths of glass tube, and subsequently the solution is drawn off through a bent glass tube slipped into one of the same connectors. The bottles, thus arranged, serve the same purpose as a soda-water syphon. The rubber stoppers soon become cemented to the glass, and are never removed, the bottles being filled as they are vented, through the glass tubes. A rubber connector with a pressure-tap must also be provided for the vent-tube of the large bottle, C, which serves, as we have said, to receive the unabsorbed gas. In charging the water, we leave the vent of this gasometer open until the air is expelled from the apparatus, and then connect the vent-tube by a rubber-hose with a manometer, which, if a common steam manometer is not at hand, can be easily extemporised with a glass tube and a little mercury. We now watch the pressure, and when it becomes equal to the water pressure on our faucet, we turn on the water head. On first opening the faucet it is necessary to watch the process very closely, lest the water should be forced back into the generator, but the apparatus soon adjusts itself to the new conditions, and the absorption goes on as regularly as before. The unabsorbed gas is, of course, stored in the bottle C, and gradually pushes back the water, with which at first it is three-fourths filled, into the supply pipe; but only a small portion of the gas is lost, and, with the apparatus of the dimensions described, a 2-gallon bottle is large enough to hold all the excess, which escapes before the water is saturated. To ensure perfect saturation, the water in each of the bottles B and C should be frequently shaken up with the gas, especially towards the end of the process.

We constantly use an apparatus mounted as above, with a water-head of about 30 feet. It would undoubtedly stand a much greater pressure, but a solution saturated under a pressure of two atmospheres is as strong as is desirable. For example, 100 c.c. of such a solution is more than sufficient to precipitate a gramme of antimony. For saturating 4 litres of water in an apparatus of the dimensions described above, the charge should be about 200 grms. of ferrous sulphide, about 2 litres of water, and 288 grms., or 160 c.c., of sulphuric acid. As this amount

of acid water, when at a low temperature, is insufficient to dissolve all the ferrous sulphate formed. we place the generator in front of a hot air register. In dismounting the apparatus, we close first the inlet-tube of the bottle B, and then remove the generator and wash-bottle; but care must be taken to relieve the pressure on the generator very slowly, otherwise the escaping gas will cause the acid solution of ferrous sulphate left in the bottle to boil over.

By the use of a solution of hydric sulphide in place of the gas, the consumption of ferrous sulphide in our large laboratory has been reduced twentyfold, and when it is remembered that by the previous waste the air of the room was constantly poisoned, and the waste-pipes clogged with the undissolved sulphide of iron, carelessly washed into the sinks, the advantage will be appreciated. The gain in those processes of quantitative analysis where hydric sulphide is required is hardly less important. The bubbling of a gas through a liquid inevitably entails loss, which can be wholly avoided by using the solution, and, by regulating the pressure on the tap, the reagent can be delivered in the proportions required, and at the exact point where it is wanted. Complete precipitation, moreover, is effected in a few minutes; and, if the liquid is constantly stirred as the reagent slowly flows in, the precipitate will settle in a condition admirably adapted for filtering. Lastly, the separation of sulphur, which is often so excessive when the gas is employed, is diminished, if not prevented, by using the reagent in solution.

THE INTERNATIONAL EXHIBITION OF 1873.

CHEMISTRY may be said either to be or not to be represented in this year's Exhibition. The products of chemistry considered as a pure science would not, perhaps, afford more pleasure nor profit to the visitor than could be obtained from a call upon his druggist. Stoppered bottles, however brilliant their contents, have very much in common; but chemistry as an applied science appears under some one or other phase in nearly every process of manufacture, and the products and processes of this year's Exhibition are consequently as interesting to the technical chemist as the exhibits of years when chemistry has been expressly included.

The products of this year are chiefly related to Food—one of the most important, if not the most important, of the applications of chemical science. For much as chemistry has done for our tables and ourselves, there still remains for it to solve the problem of the proper preservation of food. Until it has solved the problem we may never hope to see in any exhibition anything better than artificial representations of the three great staple foods—meat, vegetables, and bread. For the reason that the question is yet to be fully solved, we have in this year's Exhibition a predominance of groceries and dry-saltries. But these, although most important exhibits, have not the scientific nor utilitarian interest attaching to the preservation of flesh. Doubtless, without tea, cocoa, coffee, biscuits, confectionery, we should be badly off indeed, but it is possible to imagine existence as progressing in their absence. Flesh, however, is so universal a staple food, that without its existence to many of us would be not only a hardship, but probably impossible. Yet so rapidly does the price of fresh meat increase that daily the desideratum of providing some efficient means for its proper preservation becomes more pressing. Men have long recognised the importance of the question. As early as 1690 Messrs. John White and William Porter obtained from the Crown a right of monopoly for fourteen years in the preservation of flesh; and from that time to this many hundred patents have been taken out, the processes meeting with more or less success. Until this time the methods of preservation may be classed under four heads:—(1) Preservation by cold; (2) by drying;

(3) by removal of air; (4) and by the use of chemical antiseptics.

Preservation by cold is a naturally established fact. In the Arctic regions, Russia, and Canada slaughtered animals are buried for months in the frozen earth and ice. Our fishmongers use ice as the chief preservative of their fish, either in over-night stock, or its progress to and from market. And it has been proposed to import from South America, Australia, and elsewhere, where meat is cheap, carcasses of animals preserved in ice. Actually among the exhibits of this year there is only one of preservation by cold shown by the Atmospheric Churn Company; who, in one of their refrigerators, have some butter, fish, and a joint of meat. Messrs. Chevasse and Co. also exhibit one of their "Clifton's Patent Dry Cold-Air Refrigerators," containing the ice-chamber at the back, and feeding the food-chamber with cold air by means of valves, these valves being opened by a rod when the door is closed, and *vice versa*. External air is thus prevented entering the ice-chamber in any bulk when the doors are opened. The Piston Freezing Machine and Ice Company exhibit several of Ash's patents, the chief being the Self-Feeding Cabinet Refrigerator, arranged in such manner that the lowest temperature is available until the complete expenditure of the ice. The ice-chamber is inclined at an angle to the side of the safe, so that as the ice melts it still bears with nearly the same surface against the food-chamber. Messrs. Howe and Shoppee exhibit an "Arctic Ice Safe" lined throughout with non-conducting white glazed porcelain tiles, having the advantage of being readily cleansed. Messrs. Kent have on view one of their "Ventilated Ice Safes," constructed on the principle that cold air being heavier displaces warmer air and descends. It is stated that in such a safe mutton may be kept for a fortnight at a temperature of 40° to 45°, and a sweetbread—one of the most difficult things to keep—for a week. Cream also has been preserved for a week. Messrs. Brainard have a model of their patent ice-house, largely employed in America; and there is a very interesting model of the ice-room of the Peninsular and Oriental Company's steamship *Cathay*.

Probably the most ancient process of flesh preservation is by drying. The Egyptians preserved birds or poultry in this manner, and the American Indians have long been adepts at the preparation of "charqui" or dried beef, the "dampier" of the Australian squatter. But of this kind of preservation one does not see examples at South Kensington this year, except in the preservation of peas and vegetables together with dried and powdered meat in the form of biscuits, the chief exhibits being by Messrs. Whitehead, Messrs. Geyelin, Messrs. Warriner, Messrs. Hewetson and Co. The Prussians during the late war gave much attention to this mode of preservation, and their "Ebswurst" or portable soup is exhibited by Messrs. Johnston, who have also some meat powders. Messrs. Gillon show some dried and compressed vegetables with dried beef.

Preservation by expulsion of air is daily becoming more familiar to us, whether in the case of milk, meat, soup, or fish. This method is probably the most perfect we have, as it preserves flavour and moisture, and presents the food in a cooked form—a great benefit to the working classes. The meat, fish, or whatever is to be preserved is put into the tin in which it is to be kept, a small pin-hole being left. The tins are then immersed in chloride of calcium baths, or salt-water baths, or by other means raised to a higher temperature than the boiling-point, and the air thus expelled. From the preserving market of Aberdeen we have the greatest show of food preserved in this manner, the chief exhibitors being Messrs. Moir and Sons, who since 1822 have devoted their attention to the subject. This firm preserves as much as two-and-a-half million pounds of meat in a year, forming but a moiety of the nearly five million pounds of food put up yearly by them into tins. Messrs. Hogarth also exhibit fish and soups preserved in a similar manner in glass jars.

Messrs. Whitehead have their Australian beef and mutton and solid essences. The Ramornie Company, the first association for the sale of Australian meat, exhibit preserved Australian mock-turtle, rump-steaks, ox-tongues, beef-stew, &c., Messrs. McCall and Co. exhibit meat from Uruguay, some kangaroo-tail soup, and, indeed, kangaroo *à la mode*, and in every other mode. This firm also exhibits dried turtle for the making of real turtle soup. Messrs. Gillon, who have employed since 1817 a large number of hands in the preservation of meat, exhibit specimens of the essence of beef, condensed mutton, and chicken juices, Scotch broth, cockie-leekie, haggis, and other preserved dishes in which a Scotchman doth most delight. Then we have the Ballarat Meat Preserving Company; and, dear to the heart of Anglo-Indians, the preserved curries from Mr. Halford—*chef* to a former Governor-General of India. Two fowls here, preserved in tins, can be bought for seven and sixpence. The Food Preserving Company (late Forbes and Co.) exhibit results of Jones's patent process. In this process a vacuum apparatus is employed to withdraw the air from the tins, and by this means much of the over-cooking arising from the expelling process is avoided. A model of the apparatus is shown. Mr. Tallerman, of the Australian Meat Preserving Agency, has in the western annexe some meat actually in process of preservation on the chloride of calcium baths, and considerable exhibits of Australian veal and lamb. Of condensed milk, by the process which is now so well known to the public, there are exhibits by the Aylesbury Company, who also show coffee and cocoa combined with milk.

The preservation of meat by antiseptic processes is not illustrated in this year's Exhibition, unless we include the use of salt as an antiseptic. Chemistry does not appear to have solved the problem of preservation by means of a tasteless, innocuous agent; for of most processes hitherto known, even after much washing of the meat, there is considerable danger of the occurrence of disagreeable flavour.

Passing from Food to Confectionery we find many interesting illustrations of machinery and processes. Walking down the machinery transept the visitor's attention is attracted by immense revolving bulged-in copper vessels, in which he finds almonds and caraway seeds are in course of conversion into sugar-plums and comfits. These seeds are caused to roll over and over, and thus gradually collect a coating of the hot clarified sugar which is added to them from time to time. When a moderately thick coating of sugar has been imparted another coating is given, and when of the desired size the colouring matter is poured into the pan. The exhibits under this head are by Messrs. Allen, and by Messrs. Hill and Jones. A little further on will be found an exhibit by Messrs. Batty illustrating the method of preparing oranges for marmalade: a disintegrating flour mill by Messrs. Carr and Cunningham; and apparatus for cutting and moulding sweetened gum into jujubes by Messrs. L. Collier. Messrs. Coleman exhibit the apparatus employed in separating mustard from the seed; and the Compagnie Francaise, machinery used in the preparation of cocoa. Messrs. Criscuolo, Kay, and Co.'s machinery for the preparation of macaroni naturally is an object of interest to the visitor. It is stated that the Italian wheat from which the macaroni is prepared contains on the average 15 per cent flour, 24 per cent bran, 16, 3, and 42 per cent respectively of semolina of second, first, and superfine qualities. An ingenious method of sifting and cleaning wheat is shown by Messrs. J. N. Sears and Co. The principle consists in causing the grains to meet a blast of air by which the refuse is removed, and the heavier grain allowed to descend into the hopper.

Leaving for a time the machinery annexe we enter the Australian Court. Here the chemist will be much interested in the specimens of mineral wealth of our colonies. There are exhibits of gold imbedded in quartz, and a superb lump of malachite. The specimens of copper ore

from the Moonta mine are remarkably fine, and we understand that 18,000 tons of such ore is yielded yearly. The greater part of the ore is yellow sulphide, but there are specimens of quartz and purple sulphide ranging as high as 50 per cent, with peacock ore (copper pyrites) at 30 per cent. There are chlorides at 45 per cent; and some rare specimens of black and crystallised oxide, together with some grey sulphide, attain to 75 per cent. The Wallaroo mine sends specimens of green copper carbonate; and the Mount Balhannah mines exhibit specimens of bismuth. Kauri gum is also an interesting exhibit. This gum is obtained from swamps formerly covered by Kauri trees by spearing the ground until gum exudes. It is then dug out, and forwarded to the hands of the varnish maker.

The Victorian annexe contains further exhibits of Australian preserved food, hams and bacon, tinned meat, &c., and a very valuable attempt to preserve fresh uncooked meat in an ice-room. It is stated that a vessel under the care of Mr. Harrison, the inventor, is on her voyage to England with 100 tons of meat thus preserved on board.

In the Russian annexe, too, there are exhibits of tablets of dry meat and game prepared by M. Wladislas Kleczkowski, Messrs. Kittarg's packets of dried vegetables, dried mushrooms on strings, dried green peas, &c.

As a journal of physical and applied science, our report would not be complete without some mention of the machinery in the annexe we have already visited. A process comparatively strange to this country is to be seen in progress at the stall of Messrs. A. Jouffray, the winding of silk from the cocoon of the silkworm. The apparatus consists of a brass-topped table in which are inserted shallow turned boilers, the water in these boilers being heated by jets of steam. The operator, having thrown the cocoons into this boiling water, provides himself with a whisk-brush, and plunging this into the bath, collects on its fibres the filaments of the cocoons floating on the surface of the water. These filaments he then passes to a glass eye, whence it is carried to a reel turned by power. Then we come again to specimens of English manufacture, for the winding machines are from the hands of Messrs. Rushton, Son, and Co., of Macclesfield. From the "winder" the silk passes to the cleaning machine, which consists of two fixed plates, and between these the fibre is passed to detect knots and other irregularities. Next the fibre appears upon the doubling machine, where two or three fibres are run together side by side without twist, the result being termed "train." If the fibres are to be twisted they are taken to the fourth or spinning machine; the twist fibre given out by this machine being known as "Organzine." Near at hand there are similar machines by Messrs. Higginbotham, and a machine for recovering silk waste by Messrs. Greenwood and Batley. The Jacquard and other looms shown by Messrs. Warner, Sillet, and Ram, Messrs. Norris and Co., and by Messrs. Stevens we need not here dwell upon.

Objects well worthy attention are the ingenious devices for the production of aerated waters and for bottling the same exhibited by Messrs. Fleet and Co., Messrs. Hayward, Tyler, and Co., and by Messrs. Barnett and Foster. In these new methods of bottling advantage is taken of the expansive force exerted by the compressed gas, which is caused to hold a glass marble or wooden plug against a welt of india-rubber inserted in the neck of the bottle.

In the stoneware department we have an elegant piece of design by Messrs. Doulton and Co., whose collection of chemical apparatus was so noticeable last year. And, though very distantly allied, we have the apparatus for boring rock and stone exhibited by the Diamond Rock Boring Company, who show a "drill head" and "prospecting machine." Hard black diamonds are fitted into a collar, and the drill thus constructed is caused to rotate against the face of the rock as in other boring machines. But far the most philosophical instrument for working in stone is the sand-blast of Mr. Tilghman. The principle

of the apparatus is that a blast of air or steam is caused to carry a jet of sand against the surface to be abraded. A description of the apparatus has already appeared in these pages; and it will be necessary only to say that with a pressure of 55 lbs. 3-16ths of an inch of marble can be cut away in five minutes, and glass almost instantaneously engraved, a design cut in paper being first placed on the portion to be protected.

The department devoted to surgical instruments will be one of the greatest interest to the professional medical man, but to the general reader the instruments cannot well be described. The "Pneumatic Aspirator," for removing morbid fluids from a natural cavity, is perhaps one of the most recent improvements in medical appliances. It consists of an exhausting syringe of about 4 ozs. capacity, with an air-tight piston. The nozzle is bent at right angles, and is provided with two stopcocks. A hollow needle is affixed to the nozzle, and the piston being raised and the air exhausted from the instrument, the needle is introduced into the tumour. When a sufficient depth has been reached to prevent access of air the stopcock is turned, and the fluid by atmospheric pressure is drawn into the aspirator. The aspirator filled, the stopcock is closed, and the second cock opened; the piston is pressed down, the fluid discharged, the cock closed, the piston re-drawn, and the operation if necessary may be repeated.

Returning to the galleries of the Albert Hall, we find several inventions relating to railway signalling; which, however, we cannot efficiently describe without drawings. In one corner of this room are the Magneto-Electric Clocks exhibited by the British Telegraph Manufactory. The principle of these clocks is that of an unbroken circuit, which includes a coil of wire attached to the pendulum of the motor clock (and vibrating over permanent magnets) and the coil of the secondary clock. At each vibration of the pendulum coil of the motor clock an induced current is generated, which is transmitted to the secondary clock, where it actuates a set of rotating magnetic needles. A system of these clocks have been presented to the Royal Institution; and a set has been for some time working at the University of London, Burlington Gardens.

From a practical point of view the Exhibition of this year, attended as it will be, and is, by those really interested in its exhibits, shows elements of great success. This year we lose much that has been striking in former Exhibitions, but the gain in practical instruction, and as a record of real progress, is much enhanced. The Commissioners are certainly to be congratulated on the success of the year.

ON THE ENERGIES OF THE IMPONDERABLES, WITH ESPECIAL REFERENCE TO THE MEASUREMENT AND UTILISATION OF THEM.*

By the Rev. ARTHUR RIGG, M.A.

(Continued from p. 56).

MR. MICHAEL suggested to Cavendish an experiment which has ever since gone by the name of Cavendish's experiment, and from which was deduced the first pretty accurate calculation or actual measurement of the density of the earth. Cavendish, as you know, was a very wise man. It is said of him that "he was the richest wise man, and the wisest rich man, that the world ever saw." He left more than a million of money. He had also another quality which would be very desirable to cultivate in certain parts of this kingdom at the present time—he uttered fewer words than any other man who attained the same age is supposed to have done. He discovered many things, and, amongst others, he was the first to make an attempt

at weighing the whole earth, and he weighed it with an accuracy which has only been confirmed in recent times.

The apparatus that Cavendish used was double the size of this which you see before you, but it was similar in construction. He had two balls of lead, similar to these large ones, suspended from a very light bar, that bar being trussed, as it is called, by a kind of triangle of wires, and the whole being attached to a hook in a pulley, round which he passed a cord, by means of which the balls of lead can be moved to any position you please. In order to exclude every external influence, the apparatus was enclosed in a room of its own, and to observe the phenomena that took place within that closed room lamps were applied at small orifices, and telescopes were placed at others. In addition to this apparatus with the two balls of lead, which weighed about 3 cwt. each (as far as my memory serves), he had another apparatus placed below the other, as you see here. From a centre immediately under the pulley to which a frame carrying the leaden balls is attached, was suspended by an exceedingly fine wire a light rod with two little balls, less than bullets, and these balls held a certain position, and could not move from it beyond certain limits. Being placed in the aforesaid enclosed room, where there were no draughts or variations of temperature, or anything external to affect them, and they had been left for some time—say, for twenty-four hours, they became stationary, and would not move unless some external force were applied to them. At the end of the light bar carrying these small balls was an ivory scale and a pointer, and upon this was directed the light of a lamp from outside the room, whilst a knob was also placed outside, by turning which the motion of the large leaden balls could be controlled. At another orifice was placed a telescope, by means of which the motion of the pointer could be observed. After the little balls had become quite stationary, by the cord he very gently swung the larger balls to a position close to the small ones, and after a certain lapse of time, varying from a quarter of an hour to an hour, he observed the space through which the small balls were moved from the position they had occupied. It may be well to state that a thorough examination had been previously made as to whether any influence could be due to magnetism.

This experiment had to be repeated very frequently, because of the minuteness of the range of these balls and the magnification of it. The application of the results was to be so important. He therefore made three experiments on each occasion, and observed the position that the balls took. He also observed another matter, which is of great consequence, although this evening to be passed over very lightly, namely, the number of oscillations made by the small balls before they came to rest. These balls oscillate like a pendulum, and by the number of times they swing before coming to rest certain calculations of great importance to the inquiry may be made. These calculations being completed, the conclusion he arrived at was that the earth was 5·4 (say 5½ times) heavier than water.

Now it is only right that you should be told how from these balls the density of the earth can be deduced. The mass or quantity of matter in these balls is known; their attraction upon the little balls is known from observation. The mass, therefore, of any other ball being known, we can tell the attraction that it would have upon these balls. It is quite clear that if this large ball had double the mass it would have double the attraction at the same distance; if treble the mass, treble the attraction, and so on. Again, if the mass of the little ball was known and the attraction of the great one known, and the mass of the great one known, then if the mass of another ball is known, we shall get the attraction of that other ball. It should also be attempted to make clear how, from these two balls, we can weigh the earth, and probably it will keep your interest alive in the matter if informed that, in 1835 (Cavendish's experiments being made at the close of the last century,

* The Cantor Lectures, delivered before the Society of Arts.

about 1798), Mr. Baily, the founder of the Astronomical Society, repeated them. Mr. Baily had been a stockbroker in London; he retired from business, and purchased a house in Tavistock Place, the one, I believe, in which Mr. Digby Wyatt now lives. He there made many experiments, and some most extraordinary calculations, and did a large amount of astronomical work. Amongst other things he undertook to weigh the earth, and he weighed it as Cavendish did, namely, by an apparatus constructed on the same principle as the one before you. He swathed the box or chamber, in which the balls were, with flannel, and put a gilded cover over all. He also lined the inside with tin-foil, and connected it by a copper wire with the earth. These precautions were intended to neutralise, as far as practicable, changes in atmospheric temperature and terrestrial electricity. How important he considered it you may judge from this, that he made more than 2500 experiments with balls of this character; he sat watching them for 1200 hours, and that number of experiments extended over some years. The repetition was planned in 1835, commenced in 1837, and concluded in 1842. The result of these 1200 hours of watching, exclusive of the calculations which followed, led to the conclusion that Cavendish was right within a fraction of 2-10ths, that is to say, Cavendish concluded that the density of the earth was 5.4 times that of water; Baily concluded that it might be 5.6 times that of water.

It may be permitted to repeat the reasoning, in order if possible to make clearer the principle on which it proceeds. From the weights we know the masses of the large ball and of the small one. We know that the small balls in relation to the large ones were free from the influence of gravity; we also know by observation how much the one attracts the other. Double the ball, and you get double the attraction, and so on. Now, we know the size of the earth, and by placing this little ball on a spring balance we know how much the earth will attract it. Therefore, the weight of the little ball being known, and the size of the earth being known, there is nothing left except the attraction to find, and, as we have the attraction from these two balls, we can, by a simple arithmetical operation, determine that the earth is 5.6 heavier than water.

This seems the best opportunity to name that the present Astronomer-Royal (Professor Airy) investigated by very different means, and on very different principles, this question of how much heavier than a globe of water the earth is. Qualifying the conclusions from his experiments as himself suggests, consequent upon certain geological considerations, it may be asserted that Cavendish's result is very nearly correct.

Time passed by; Cavendish's experiment was made, as I told you, about 1798, and Baily repeated it about 1835. We must now go back, as a matter of history, to Cavendish's time, and the next step we arrive at in determining the energy of gravity was the experiment that was made by Atwood, who was born in 1746. He was a Fellow of Trinity College, Cambridge, and was the first to entertain the idea of devising some plan of measuring the force of gravity. Let me endeavour to make this matter clear. Cavendish determined the density of the earth, but he did nothing whatever as to determining the force of gravity. Force, as stated in the first lecture, can only be measured by motion. We can easily obtain motion from the action of gravity, but we must observe that motion in order to measure force. If a weight be let fall, it falls far too quickly to permit of an estimate of the rate at which it falls. That rate is due to gravity. Atwood thought, as Galileo had previously done, that by causing the fall to be delayed, he might be able to draw a conclusion as to the exact force of gravity, and the plan he adopted was this. You are aware that the intervals between the ticks of a pendulum vary according to its length. Here is a pendulum, and you see the rate at which it is going;

if, now, the pendulum-weight be lowered, so as to lengthen the rod, you may observe that the pendulum ticks more slowly—in fact, it is now beating seconds. You were told, in the first lecture, that we must have a certain unit of measurement, and the *second* is the unit of measurement usually taken for time. If we want smaller measurements, for it is easy to divide the second into a hundred parts, they are taken by another contrivance. A very simple and efficient one is a clepsydra, or water-clock, arranged specially for this purpose.

What Atwood thought of doing in order to measure the force of gravity, having, you remember, no previous measurements to guide him (for Galileo did not touch the problem that Atwood proposed to solve), was to take two weights evenly balanced over pulleys such as these, the apparatus being most delicately made. You see that these two small weights are exactly balanced, one being at each end of a cord which passes over pulleys at the top of the apparatus, so that the weight in descending passes down in front of a graduated scale. These weights, then, are exactly balanced. Here are three very small weights, fractional parts of the ones which are suspended. If one of these small weights falls by itself, it would fall so rapidly that its rate of falling could not be observed; but if, whilst it is falling, it is caused to bring this mass of matter with it, the rate of falling will be retarded, whilst the law of the rate remains the same, *i.e.*, the law which governs the rate of falling will be similar, although the mass moved is increased. If now there be placed upon one of these balanced weights two of these little fractional weights, there is a something that will cause the connected mass to move, and this platform at the bottom will be struck about four seconds after the motion commences. The usual plan is to let the motion be commenced by electricity, which at the same time sets the pendulum in motion. You can count the strokes of the pendulum from the commencement to the end of the motion. You can see this mass of matter has been moved through eighteen spaces in four seconds. If the measure be altered, you will readily understand that these fractional weights would carry it through a different space in the same time; if other weights be put on, they would carry it through other spaces. The experiment, as made before the apparatus was brought here, shows that the force of gravity is such as to cause a body to fall through about 32 feet in one second, the meaning being that if this small weight had not been required to bring the other weights along with it, then it would have fallen from rest through 32 feet in the first second. That was the first attempt of estimating by measurement the force of gravity.

But Atwood's apparatus, though exceedingly good as matter of illustration, falls very far short indeed of that which Captain Kater adopted; and all that we have, and all that we know, of the form of the earth, and the true kinetic measure of gravity, spring from Kater's experiments, and not from either Cavendish's, Baily's, or Atwood's. Kater felt that, if instead of weights falling as they have fallen in the experiments of Atwood, he could observe the effect of gravity upon the weight falling without associating it with other weights, if it could be kept quite distinct, and if in any way he could cause gravity to repeat the operation slowly and deliberately, without any interference whatever, we might get at the conclusion much more rapidly than Atwood could by his arrangement, because the friction of the wheels, the weight of the cord, and other incidental matters affect the problem. What Kater did was to design a pendulum, of which this is a copy. It was from a pendulum like this that not only was the force of gravity determined in all parts of England, but also the form of the earth itself has been decided and estimated. Our standards of weights and measures all come from a pendulum like this. If, in

fact, the standards were all lost, it would be from such a pendulum they must be restored. Let me anticipate the conclusion by stating that when the standards were lost in the burning of the houses of Parliament they were restored by seeking for copies, because the great number of corrections and the great difficulty of counting this pendulum and freeing it from interfering causes are very serious obstacles. Few are aware of the enormous difficulty there is in placing a pendulum so as to be free from external influences, and counting the oscillations of it.

Whilst upon weights and measures, your attention may be directed to a small piece of wood here, which is a model of the standard one pound weight of Great Britain. It is one which a committee of learned men obtained, and this in my hand is a copy. The real standard is made of platinum. It is a cylinder 1.35 inches high and 1.15 inches in diameter. Observe there is a groove turned in it, and there is an ivory fork by which it is to be lifted—these standards are not to be touched. There are only five of them made, and if ever the one pound weight is lost in England it is to be recovered, not by repeating Kater's experiments, but by copying one or other of these five standards. The five are kept—one at the Exchequer Chambers at Westminster, one at the Royal Mint, one with the Royal Society, one at the Royal Observatory, Greenwich, and one is immersed in the sill of the recess on the east side of the lower waiting-hall of the New Palace at Westminster.

(To be continued.)

CORRESPONDENCE.

ON THE ESTIMATION OF MAGNESIUM AS PYROPHOSPHATE.

To the Editor of the Chemical News.

SIR,—In your last issue I observed a paper, communicated by Dr. Gibbs, suggesting the substitution of ammonium-hydrogen-sodium phosphate, $\text{NH}_4\text{HNa}(\text{PO}_4)$ (micro-cosmic salt) for the ordinary sodium phosphate, as a precipitant for magnesium. Might I add a few remarks upon this subject? Some four or five months ago, at the suggestion of Dr. W. Ramsay, I undertook a series of experiments with a view to ascertain whether or not this mode of procedure would yield good results. In my first experiments I precipitated the magnesium from a cold solution of magnesium sulphate containing ammonium chloride, but failed in obtaining results which could be considered as satisfactory. In my subsequent experiments I heated the mixed solutions of magnesium sulphate and ammonium chloride to the boiling-point, and precipitated the magnesium from the boiling liquid by adding the $\text{NH}_4\text{HNa}(\text{PO}_4)$ solution. After having been allowed to cool, ammonium hydrate was added, and the whole allowed to stand for twenty-four hours. The precipitate of $\text{MgNH}_4(\text{PO}_4) \cdot 6\text{H}_2\text{O}$ was then collected upon a filter, dried at 100°C ., ignited, and weighed as $\text{Mg}_2\text{P}_2\text{O}_7$ in the usual manner. The following figures will serve to illustrate the accuracy of this process:—

Grms.	Grm.	Grm.
1.0020 $\text{MgSO}_4 + 7\text{H}_2\text{O}$	$= 0.4850$	$\text{Mg}_2\text{P}_2\text{O}_7 = 0.0985$ $\text{Mg} = 9.83$ per cent.
1.0321 "	$= 0.4675$ "	$= 0.1011$ " $= 9.78$ "
1.3820 "	$= 0.6264$ "	$= 0.1354$ " $= 9.79$ "
1.0022 "	$= 0.4561$ "	$= 0.0986$ " $= 9.84$ "

The mean results being 9.81 per cent. As $\text{MgSO}_4 + 7\text{H}_2\text{O}$, theoretically speaking, requires 9.76 per cent of Mg, this leaves an average error of about 0.04. As magnesium is a substance which analysts have frequent occasion to estimate, Dr. Gibbs's suggestions are well worthy of their consideration. For my part I can heartily recommend his process.—I am, &c.,

R. W. EMERSON McIVOR.

Glasgow, August 4, 1873.

ADULTERATION OF BUTTER.

To the Editor of the Chemical News.

SIR,—I am taking a lively interest in the discussion on the method of detecting the adulteration of butter, and am glad that Mr. Horsley has written to remind your readers of his previous work on the subject. I have found his process very useful and practical, and have used it to a considerable extent. A simple way of applying the ether method is the following, which I copy from an article on the "Detection of Adulteration of Butter," contributed by me to the *English Mechanic* during the autumn of last year:—

"Animal fats in butter are best detected by shaking a small portion of the sample with a moderate quantity of ether, in a corked tube, at the ordinary temperature, when the butter will readily dissolve, and leave the adulterating fat as a milky fluid at the bottom of the tube: the residue when due to lard is pretty fluid, but that left by tallow or dripping has a peculiar, thick, granular appearance. The upper liquid should be poured off, and the residue washed once or twice with a little cold ether, when it may be examined under the microscope, and tasted, after warming to get rid of adherent ether. If the test be made on a mixture of pure butter with lard, tallow, dripping, &c., a few trials will show that it is capable of giving very fair results. Excess of ether must be avoided, or complete solution will take place. If the butter contains much salt or water, it is best to purify it first by melting and shaking with hot water."

The success of the test evidently depends on the sparing solubility of stearin in cold ether. Dr. Campbell Brown's method is a more refined application of the same principle. The taste of the residuary fat is quite characteristic. Pure butter sometimes leaves a slight residue, but it is free from any taste of animal fat. Although the analyst employing the above test may possibly fail in detecting a small admixture of lard, he can scarcely miss dripping or tallow, 5 per cent of the latter fat being readily recognised by the method described. The test also furnishes unscientific persons with a convincing proof of the adulteration, a fact which is not without its value.

Of course, as above described, the test makes no pretension to scientific accuracy, but by the use of definite weights of butter and ether it forms a very valuable adjunct to (and in some cases a substitute for) the more elaborate methods recently proposed.—I am, &c.,

ALFRED H. ALLEN, F.C.S.

Borough Analyst's Laboratory, Sheffield,
August 5, 1873.

University of London.—The following is a list of the Candidates who have passed the recent B.Sc. Examination:—*First Division*.—Peter Phillips Bedson, Owens College; Edward Boyce Cumberland, private study; Thomas Frederick Harris, private study; Samuel Alexander Hill, Royal School of Mines; William Hudson, private study; John Viriamu Jones, University College; Oliver Joseph Lodge, private study; James Gordon MacGregor, Edinburgh University; William Rushton Parker, Caius College, Cambridge; Thomas Slater Tait, Owens College; Claude Metford Thompson, University College; Arthur Thomas Wilkinson, B.A., Wesleyan College, Taunton. *Second Division*.—William Brown, Birkbeck Institution; George Christopher, University College; George Simmonds Dunn, B.A., private study; John Gilliott Garbutt, M.A., St. Mary's Hospital; Charles Hopkinson, Owens College; Peter Horrocks, Owens College; John Neville Keynes, B.A., Pembroke, Cambridge, and University Colleges; William Henry Munns, B.A., University College; Frank Prior Purvis, private study; Prasanna Kumār Ráy, University College; Charles Robinson, Owens College; Herbert Robson, University College; Alexander Simpson, B.A., F. C. Divinity Hall, Aberdeen; Arthur Hewett Spokes, B.A., University College; Charles Alfred Weber, B.A., University College.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Under this heading will be found an encyclopaedic list of chemical papers published abroad during the past week, with abstracts of all susceptible of advantageous abridgment. The two half-yearly volumes of the CHEMICAL NEWS, with their copious indices, will, therefore, be equivalent to an English edition of the "Jahresberichte."

NOTE. All degrees of temperature are Centigrade, unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances de l'Académie des Sciences, July 14, 1873.

Mode of Intervention of Water in Chemical Action during the Mixture of Saline Solutions, whether Neutral, Acid, or Alkaline.—M. Becquerel.—The author draws the following conclusions from his experiments:—(1). In the mixture of two neutral saline solutions giving rise to double decompositions, these decompositions are brought about by the intervention of the reactions of water on the constituents of the salts. (2). In the reaction of acid upon alkaline solutions, water is still the principal agent by whose intermediation it is effected. The affinity of acid and alkali, both anhydrous, plays only a feeble part in the production of electromotive forces.

Thermic Researches on Saline Solutions.—P. A. Favre.—A thermo-chemical paper in continuation of the controversy now pending between Professor Thomsen on the one hand and certain French savants on the other.

Reduction of Platinum Salts by Hydrogen Gas.—M. Merget.—The author finds that salts of platinum, like those of silver, cannot be reduced by a current of pure hydrogen. If a trace of arsenic is present the reduction takes place.

Dissociation of Red Oxide of Mercury.—H. Debray.—M. Myers, who has recently investigated the same subject, has inferred that the dissociation of oxide of mercury up to a limit of 400° is quite normal, but that the tension reached does not lessen on cooling. Above 400° there is no longer a maximum tension, the decomposition becoming total after a sufficient time. The author does not consider this view justified by the experimental results of M. Myers.

Oxalines or Ethers of Glycerin and of the Polyatomic Alcohols.—M. Lorin.—Oxalic acid and glycerin give rise to oxalin, a solid white body, silky, like acetamide, hygrometric, and of a fatty aspect. If heated, it melts, gives off vapours, liberates carbonic oxide, and leaves a residue of glycerin. Ammonia converts oxalin into oxamide. Oxalic acid yields a compound resembling mannite. The author has previously pointed out the formation of a substance of the same type, resulting from the action of oxalic acid upon glycol.

"Turbinage" of Frozen Wines.—M. Melsens.—Alcohol is totally absent in ice produced in the midst of vinous liquids. The turbine used in sugar refineries to separate the crystals of sugar from the treacle is the best instrument for separating this ice from the concentrated wine.

Theory of the Planet Saturn.—M. Le Verrier.—This forms the twenty-first chapter of the author's "*Recherches Astronomiques*."

Note on the Isochronous Regulator constructed by M. Breguet for Observation of the Transit of Venus at Yokohama.—M. Yvon Villarceau.—This instrument appears in the Vienna Exhibition.

Modifications of the Magnetic Power of Steel by Tempering and Annealing.—M. Jamin.—Soft iron takes the greatest temporary magnetism; tempered steel receives much less; and the less, the greater the hardening

effect produced. A hard bar of cast steel, annealed to red, gave a separative force of 1290 grms. for a current of twelve elements. Hardened and subjected to the same conditions, it showed a force of only 75 grms. Steels of good quality, in thin plates and greatly hardened, are absolutely unfit to become permanent magnets; poor steels retain the polarity, and may be made powerful magnets after great hardening, and without annealing. All kinds of steel attain a maximum for their co-efficient of polarity, but in different conditions; poor or average steels, after rigid hardening; rich or refractory steels, greatly hardened, after a measure of re-heating, the temperature of which is higher in proportion to the degree of previous hardening. If one wishes, with a given steel, to make the best possible magnets, this maximum must be reached, and so different steels must be differently treated, as described. There is no fixed rule (as to degree), but the particular treatment can be readily ascertained from previous treatment of a specimen. The author gives a table of values of magnetic power and co-efficient of polarity for various steels.

Degree of Visibility which can be Reached with Astronomical Telescopes of Small Dimensions.—M. D'Abbadie.

Direct Demonstration of the Fundamental Principles of Thermo-Dynamics; Laws of Friction and Impact according to this Science.—M. Lédier.—The author starts from the distinction between the motion of the *ensemble* of a system and the proper motion of its atoms; the latter being resolved into motion corresponding to change of volume in the body and vibratory motion. Having examined the various movements of atoms, he ranges the forces actuating them in three categories: (1) those measurable physically, among which are gravity, muscular force, pressure of fluids against the sides of vessels, &c.; (2) irregular molecular forces, such as act between the atoms of solid bodies; and (3) irregular or erratic molecular forces, first among which are the forces called calorific.

Note on Magnetism.—M. Du Moncel.—This refers to a recent experiment by M. Gauguain. When a soft iron armature is applied to the polar faces of a horse-shoe magnet, the magnetisation, shown by induction currents, is found increased throughout the extent of the magnet, even to the curve. He thought this to be at variance with the general idea of magnetic condensation. M. Du Moncel thinks he here confounds two different magnetic actions; one is a dynamic action, operating as in Ampère's solenoids, the centre of which corresponds to the middle of the magnetised core; and to this belong the effects of induction produced by magnets, and the attractive forces between them and the currents. The other is a static action, constituting the attractive force proper and the magnetic polarities. These two actions may be produced independently of each other. The magnetic condensation, which M. Gauguain disputes, is the result of the polar action. It is a sort of reflex action between the armature and the pole, not displacing the magnetism from one end of the magnet to the other, but calling forth, molecularly, a greater quantity of magnetism, and producing a change of orientation in the axes of the atomic polarities of magnetic molecules, which form the series of currents of the magnetic helix. Two consequences flow from this. First, the atomic polarities being super-excited, the molecular currents have more energy, and the magnetic solenoid acts with greater intensity; hence the increase of the induced currents. Second, the polarities determining attraction being displaced or concealed more or less by the reflex action of the armature, all the atomic polarities in the different parts of the magnet are displaced in the same way, in order to equilibrium. Hence, there is either a general weakening in the external polarities of the magnet when its two poles are in contact with the armature, or a weakening of one pole and strengthening of the other when the armature is in contact with one pole only. The

author adds some further proofs of magnetic condensation, or of the prolonged concentration of magnetic polar actions at the surface of contact of two magnetic pieces. One of the most curious consequences of magnetic condensation is the retardation of the current of demagnetisation in a closed magnetic system, when one interrupts the voltaic current magnetising the system.

Variable Period in Closing of a Voltaic Circuit.—M. Cazin.—The result of experiment is stated in the following proposition:—Consider a voltaic circuit, the homogeneous wire of which presents some portions straight and some wound in spiral. If we call V the potential at one point, and x the distance from this to some other point in the circuit, reckoned along the wire, the differential co-efficient $\frac{dV}{dx}$ has at each instant the same value at different points of the straight portions; it increases gradually with the time. Remaining the same at different points of the wound portion, the elements of which are subject to equal inductive actions, the co-efficient increases at first very rapidly with the time, reaches a maximum, and decreases continually till it has the same value as in the straight portions; the permanent state is then reached. Thus, in the variable period of closure, $\frac{dV}{dx}$ is not a function of the time alone; it depends on x , and on the manner in which the circulations are disposed at the point considered. It is, further, proportional to intensity of current.

On a Barometer called Absolute.—MM. Hans and Hermany.—The principle is that of observing the motion of a point in the line joining the extremities of the columns in two parallel-placed thermometers, one air, the other mercury.

On a Means of Comparing Powders with one Another.—M. de Tromenec.—The author explodes different kinds of powder by electricity, within a vessel enclosed in a larger vessel filled with water, and which serves as a calorimeter. The exploding body producing no dynamic effect the force is transformed into heat, which when measured indicates the absolute force of the powder.

Researches on the History of Digestion in Birds. M. Jobert.—The gizzard is not exclusively a triturating organ but a chemical stomach, which secretes an acid liquid.

Observations on some Liquids of the Organism of Fishes, of Crustacea, and of Cephalopoda.—MM. Rabuteau and Papillon.—The authors found urea and methylamin in the peritoneal liquid of the ray, squal, torpedo, and other fishes. Chlorhydric acid was obtained from the gastric juice of the ray. The blood of the poulp and the crab gives no absorption band in the spectroscop, becomes slightly blue in air, and loses the blue tint when carbonic acid is passed through it, resuming it when again agitated with air. It contains some urea, but the blood of the squal and ray contain a much larger proportion.

Heat of Combustion of Explosive Matters.—MM. Roux and Sarrau.

Revue Universelle des Mines, de la Metallurgie, des Travaux Publics, des Sciences et des Arts Appliqués à l'Industrie, March and April, 1873.

On Forms of the Hot-Blast Apparatus.—M. L. Gruner.—A mechanical paper.

Reply to M. Leseure's Note on the Memoir of Bochkoltz.—A controversial paper on the "Regenerator of Force."

Condition of Mines in the Island of Sardinia.—M. Sella.—A detailed account of the lead and zinc mines in that island, with analyses of the chief kinds of ore.

Conditions under which Supersilicated Cast Metal is produced in Blast-Furnaces.—Samson Jordan.—This paper has been previously extracted.

Auriferous Region of Frasconi.—C. Sagey.—The mineral contains, on an average, 105 grms. of gold and 62 of silver per ton, representing a value of 369 francs.

New Methods of Determining Iron and Alkalies Volumetrically.—P. Charpentier.—These methods are based on the employment of alkaline sulphocyanides, and on the well-known reaction ensuing when they are brought in contact with a per-salt of iron. If, into the red liquid formed by adding a solution of an alkaline sulphocyanide to a solution of a per-salt of iron, there be poured a caustic alkali, the red colour disappears, peroxide of iron is thrown down, the alkaline sulphocyanide being re-constituted. Other things being equal, it is necessary to add so much the more alkali the more iron there is in the original solution. To titrate the alkaline liquid employed in the operation, dissolve 5 decigrms. of pure iron in very dilute hydrochloric acid. It is very important that this solution is exempt from free acid, and that all the iron is in the state of sesquioxide, the latter condition being attained better by means of chlorate of potash than of nitric acid. This solution is diluted with water to the volume of a litre. Of this, 100 c.c. are placed in a white porcelain capsule, and a few drops of sulphocyanide of potassium are added, when the liquid takes a deep blood-red colour. By means of a graduated burette, caustic potash is then added, of such a strength that about a buretteful would be required to saturate a litre of the iron solution. The red liquid becomes gradually turbid, and then suddenly grows colourless, whilst the sesquioxide of iron is precipitated. The amount of alkali consumed is read off. The same alkali is then used to titrate the remaining 900 c.c. of iron solution. The number of degrees, increased by $\frac{1}{10}$, is the strength of the alkali sought for. These points being arranged, in order to analyse any ferruginous matter—whether ore, slag, or mineral water—a neutral solution in water or hydrochloric acid is prepared, diluted to a litre, and, after the addition of sulphocyanide of potassium, is titrated as above. If the number of degrees found is N' , then $\frac{N'}{N}$ is the

proportion of iron in the body under examination, N being the number of degrees of alkali required for the standard iron solution. In case of a mixture of protoxide and sesquioxide, commence by determining the pre-existing sesquioxide as above, avoiding contact with air, and adding chloride of ammonium to hinder the precipitation of protoxide of iron. A second portion is then perfectly peroxidised, and the total iron is determined. The difference shows the amount of protoxide. In this case, it is advantageous to replace the potash with ammonia. If desired, the iron solution may also be poured into a known and fixed amount of alkali, mixed with sulphocyanide. The appearance, not the disappearance, of the red colour is here decisive. After the application of this method to any given sample, the analysis can, if required, be completed by the ordinary gravimetric method. If the substance under examination contains substances precipitable by ammonia, and this alkali is employed, their precipitation may be hindered by means of chloride of ammonium; such substances are—Lithia, baryta, strontia, lime, magnesia; the protoxides of manganese, iron, zinc, cobalt; oxides of cadmium, silver, platinum, rhodium, osmium, and ruthenium. The following oxides are not thrown down by an excess of potash:—Lithia, baryta, strontia, alumina, glucina, oxides of zinc, chrome, lead, platinum, tin, palladium, rhodium, osmium, and gold. In this case, potash is employed as the standard alkali. In most cases, foreign substances do not interfere. This holds good with silica, the alkaline metals, the alkaline earths, alumina, manganese, zinc, cobalt, nickel, cadmium, chrome, lead, bismuth, silver, and all metals which give white precipitates with alkaline sulphocyanides. The application of the method to alkalimetry is based upon the following reaction:—If an excess of caustic alkali is present in a liquid along with a little sesquioxide

of iron recently precipitated, and if hydrochloric acid is gradually added, as soon as the alkali is saturated, the oxide of iron is attacked, and a ferric solution formed, which immediately gives a blood-red colouration, an alkaline sulphocyanide having been added as indicator. The method is, of course, acidimetric as well as alkalimetric. The author thinks that the method can be extended to the determination of silver, chlorine, and lime.

Revue Hebdomadaire de Chimie Scientifique et Industrielle, par Ch. Mène, No. 50, August 19, 1872.

New Mode of Silvering Glass.—M. Siemens.—Aldehyd has been long ago employed for silvering glass by Liebig's process, though the difficulties of manipulation are considerable. Siemens has improved the process by treating aldehyd with thoroughly dry ammoniacal gas. Of this liquid 2.5 grms., and 4 grms. nitrate of silver, are taken, and each is dissolved separately in water, the total amount of which is 1 litre. The two solutions are then mixed and filtered. The object to be silvered, cleaned so as to be quite free from grease, is immersed in the liquid, and heated gradually up to 50°. When this point is reached, the deposition of the metal begins in a very thin layer, dark at first, but gradually acquiring the metallic lustre. As soon as the incrustation has acquired the ordinary whiteness and lustre, the object is withdrawn from the liquid.

New Process for Preparing Anthracen.—When coal-tar is distilled with a view to the preparation of anthracen, it is necessary to push the process to its farthest limit; that is, to separate from the tar the largest possible amount of heavy oils in which alone the anthracen is found. The process hitherto employed has failed in extracting from the tar a quantity of oil containing anthracen at all proportionate to what exists in the mass. In fact, when, over and above the light oils, a quantity of heavy oils have been withdrawn equal to about one-fourth of the weight of the tar placed in the still, the operation is stopped, since the residual matter becomes viscid, and, conducting heat badly, tends to undergo decomposition and carbonisation, to the great detriment of the apparatus, which would be rapidly destroyed if the operation were further prolonged. The residue contains a large quantity of anthracen, which has hitherto been wasted. The new process consists in the use of agitators, by means of which the yield of heavy oils is raised to 40 per cent, showing a gain of 10 to 15 above the old process. The last portions of heavy oil, moreover, are richer in anthracen than the former.

Varnish or Size from Gum-Lac.—The solvent employed is carbonate of ammonia, in which the ground gum-lac is boiled till the ammoniacal odour has disappeared. It is recommended as a dressing for dark coloured textile fabrics.

Continuous Furnace for Burning Bricks, &c.—M. Easer.—A paper derived from English sources.

Improved System of Heating Gas-Retorts.—M. Rouget.—The author attains an economy of coke to the extent of 11 per cent, by arrangements calculated to intercept the radiation of heat from the front of the furnace and from the heads of the retorts.

Influence of India-Rubber Tubes on the Illuminating Power of Gas.—M. Zulkowski.—The author shows that olefiant gas and hydrocarbon vapours are absorbed by caoutchouc. Hence, tubes of this material are not admissible in experiments on the illuminating power of gas.

Use of Steam in Extinguishing Fires.—As a means extinguishing fires, the author recommends the use of large pipes, communicating with a boiler, and capable of filling the building with steam in case of a conflagration.

Anthracen Blue.—M. Springmühl.—We have recently noticed this alleged novelty.

Scarlet Dye on Cotton with Magenta.—The cotton is first to be worked in a boiling decoction of sumac and turmeric, and then with the addition, after a few hours, of a little sulphuric acid. It is then, after cooling and washing, dyed in a luke-warm bath of magenta. (It is absurd to expect a good scarlet from any combination in which magenta is present. All magentas are more or less on the blue side of red, and even the slightest admixture of blue is fatal to scarlets).

New Galvanic Pile.—M. Chauderay.—The arrangement is intended for military telegraphic purposes.

Dyeing Wax Candles Black.—M. Böttger.—This effect is produced by heating the wax along with Anacardium nuts.

Imitation of Leather.—A mixture recommended consists of 16 parts of gelatin and 5 of glycerin. A colouring matter is then added as may be required, caoutchouc to give elasticity, and boiled linseed oil to render the whole sufficiently flexible. This composition is spread upon linen whilst hot, printed with any pattern desired. The surface is then treated with a solution of alum, sulphate of iron, copper, or zinc. These saline solutions may likewise be mixed with the composition before it is spread on the linen. The surface is lastly varnished, and may be bronzed or gilt. Another composition is obtained by boiling linseed oil with quick-lime and borax, which forms a liquid that, on cooling, becomes a thick paste. It is then mixed with rasped cork and more quick-lime.

Rapid Process for Reducing Old Silver (Photographic) Baths.—M. de Krueger.—The mixed silver residues are well shaken up with phosphoric ether, when a black precipitate is deposited, which is filtered off, washed, and boiled in a strong potash lye, yielding metallic silver.

Removal of Potassic Salts from the Solutions Obtained in the Manufacture of Beet-Root Sugar.—Messrs. Duncan and Newlands.—The patentees claim the separation of potash and ammonia by the employment of tartaric acid or acid tartrates, and the separation of the same bases by means of sulphate of alumina.

Archiv für Pharmacie, Band ii., Heft 6.

Microscopic Examination of Spring Water.—E. Reichardt.

On Sugar in the Roots of Grass, and on Triticin—A New Hydrate of Carbon from the Roots of Triticum.—Herm. Müller.

Examination of Aqua Amygdali.—A. Koster.

Amount of Copper in Water passed through Copper Service Pipes.—E. Reichardt.

Examination of Sausages Coloured with Anilines.—E. Reichardt.

PATENTS.

ABRIDGMENTS OF PROVISIONAL AND COMPLETE SPECIFICATIONS.

Improvements in the manufacture of salt, and in apparatus employed therein. Robert Williamson, salt manufacturer, and Josiah Dale, manager, Wincham saltworks, Northwich, Chester. December 28, 1872.—No. 3939. First. Brine is evaporated by steam applied directly to the upper bottom of a pan, called pan A, such steam being generated in a water contained within a double bottom, the fire or flames and heating gases acting on the water-covered outer bottom. Second. Steam from pan A, or other steam, is led through a series of pipes in an other pan, called pan B, such pipes being movable up and down, centre steam-tight joints being provided. Third. The movable pipes under the above second part are balanced by chains and weights over pulleys. Fourth. Hot brine is supplied to pans by the feed pipe being led through hot water. Fifth. Brine, hot or cold, is supplied to pans through small apertures in pipes, or through a series of small nozzles.

Improvements in treating waste liquors containing arsenical or phosphatic compounds, and in obtaining and applying useful products therefrom. James Higgin, Manchester, and John Stenhouse, Pentonville, Middlesex. December 30, 1872.—No. 3949. We precipitate arseniates, arsenites, or phosphates from the waste liquors resulting from the so-called "dunging" process, applied for the fixation of mordants on textile fabrics and yarns, by an addition of muriate of lime or other suitable earthy or metallic salt, and, after collecting the precipitate on a filter, decompose it by carbonate of soda or other suitable alkaline salt, reproducing thereby a liquid or salt similar to that originally employed for the "dunging" process. We can, where preferable, precipitate insoluble arseniates, arsenites, or phosphates at the same time as fatty and colouring precipitates, by running the waste soap liquor and the waste "dunging" liquor into the same pit, and precipitate the mixed liquors by muriate of lime or other suitable agent, dissolving out from this precipitate the arsenites, arseniates, or phosphates by a suitable acid, and from this solution, by addition of lime or other alkaline agent, we obtain a precipitate, upon which we operate in the same manner as the precipitate from waste "dunging" liquor alone. We treat the fatty compound left, by one of the processes described in the Specification of Letters Patent granted to John Thom and John Stenhouse, dated July 22, 1872, No. 2186.

Improvements in the treatment of maize and other like grain for the production of starch therefrom, and in the utilisation of the waste products for the manufacture of cardboard and paper, and for the preparation of soaps. John Henry Johnson, 47, Lincoln's Inn Fields, Middlesex. (A communication from Eugène Leconte, Paris). December 30, 1872.—No. 3956. This invention consists of a process for obtaining starch in a rapid and economical manner from maize by mechanical means, and in applying the ligneous residues or products to the manufacture of paper-pulp, and the fatty products to the preparation of soap. The essential feature of the process is the entire and complete separation of the three component elements of the maize, viz., the starch, the ligneous and fibrous matters, and the fatty azotised matters.

Improvements in the production of iron. John Watson Spence, Newcastle-on-Tyne. December 30, 1872.—No. 3957. This invention consists in the production of iron by bringing reducing gases, or, if necessary, gases and air, under pressure in contact with oxides, or oxides and fluxes, or oxides, fluxes, and carbonising materials, in a furnace or reducing chamber, where they have previously, or not, been brought to a temperature sufficiently high to enable combination to take place, thereby reducing metals from their oxides direct as a successful commercial operation.

Improvements in the treatment of paper and other materials for the production of imitation or artificial leather. John Harrington, Ryde,

Ile of Wight. December 31, 1872.—No. 3959. The invention consists in taking strong paper, and staining or dyeing it to any desired colour as a ground colour, and then colouring the surface thereof to the tint required; the paper is then glazed, and afterwards waterproofed by the application of a solution of shellac thereto. In certain cases glycerine is applied to the paper to produce a great degree of pliability; or, in some cases, the glycerine may be mixed with the dye. The paper is then, if preferred, grained as described in Specification of Patent No. 2423, 1872.

New or improved methods, processes, and apparatus for depositing upon wrought-iron, steel, and cast-iron, layers of copper or alloys of copper. John Henry Johnson, 47, Lincoln's Inn Fields, Middlesex. (A communication from Octave Gaudin, chemist, Jean Baptiste, Java Mignon, and Stanislas Henry Rouart, builders, all of Paris). December 31, 1872.—No. 3970. This invention relates to different processes and apparatus for deposition on wrought-iron, steel, or cast-iron, coats or seams more or less thick, but adherent and continuous, of copper and alloys of copper. The said processes may be summed up as follows:—1st. A dry process, and the necessary apparatus peculiarly applicable for depositing thick seams of metal, as on printing cylinders, machine chairs, &c. 2nd. A dry process of precipitation, with or without using electricity, based on the decomposition of simple or compound salts of copper kept in fusion. 3rd. A humid process of precipitation of copper and of its alloys, with or without using electricity.

NOTES AND QUERIES.

Cyanides in Gas Waste Products.—Nitrous Acid from Sulphuric Acid Chambers.—I see mention made in Wagner's "Technology" of method of utilising the cyanides in gas waste products. In the *CHEMICAL NEWS* it is stated that lime has been successfully used for the collection of the escaping nitrous acid from sulphuric acid chambers. Can your readers inform me if I can obtain full particulars of these processes from any source?—ENQUIRE.

TO CORRESPONDENTS.

E. W.—Communications for "Notes and Queries" column are for the benefit of the readers of the *CHEMICAL NEWS*. Purely business communications must be made known, in the usual manner, through our advertisement columns.

South London School of Chemistry and Pharmacy. Director—Dr. JOHN MUTER, F.C.S.

Hours of Lecture for Session 1872-73:—

Chemistry (Inorganic)	10 a.m.	Materia Medica	4 p.m.
(Organic)	2 p.m.	Pharmacy	2 p.m.
Botany (Structural)	11 a.m.	Classics (Junior)	9 a.m.
(Systematic)	3 p.m.	(Senior)	4 p.m.

"Laboratory open for Practical Chemistry from 10 till 4.

This School affords the most eligible opportunities for obtaining at once a rapid, complete, and practical knowledge of the subjects taught. All the fees are perpetual until the examination in view is passed, without reference to time. Country Students visiting London are placed in Lodgings registered by the Secretary, where no impositions are permitted to be practised, and where the prices are all on a fixed moderate scale. For terms, apply to the Director, or to

W. BAXTER, Secretary.

231 and 285, Kennington Road, S.E.

BERNERS COLLEGE OF CHEMISTRY.—

EXPERIMENTAL MILITARY and NAVAL SCIENCES, under the direction of Professor E. V. GARDNER, F.R.S., &c., of the late Royal Polytechnic Institution and the Royal Naval College.

The Laboratory and Class Rooms are open from 11 to 5 a.m., and from 7 to 10 p.m. daily.

Special facilities for persons preparing for Government and other examinations.

Private Pupils will find every convenience.

Analyses, Assays, and Practical Investigations connected with Patents, &c., conducted.

For prospectus, &c., apply to Prof. E. V. G., 44, Berners-street, W.

THE LIVERPOOL COLLEGE OF CHEMISTRY, 96, DUKE STREET, LIVERPOOL.

Specially Devoted to the Study of CHEMISTRY, TECHNOLOGY and ASSAYING.

Laboratories open throughout the Year.

MARTIN MURPHY, F.C.S., &c., Principal (Successor to the late Dr. SHERIDAN MURPHY).

A Special Laboratory is devoted to Commercial Analyses of every description, and to Mineral Assays.

Manufacturers' and Smelters' Analyses and Assays undertaken on Contract.

Patentees and Inventors Advised and Assisted. Works and Mines Inspected. The Erection of Manufacturers' Plant Supervised, &c.

Terms and Fees VERY MODERATE.

Further Particulars and Full Prospectus on application to The Principal, MARTIN MURPHY, F.C.S. &c.

INSULATED ELECTRICAL WIRES.

J. & W. RICKARD,
ASHBOURNE ROAD MILLS, DERBY,

Manufacture all kinds of Silk and Cotton-Covered Copper Wires. Thorough Insulation. Conductivity 90 per cent guaranteed.

Admission, 1s.

THE CHEMICAL NEWS.

Vol. XXVIII. No. 716.

THE CHEMICAL CONSTITUTION OF SUCCINIC MALIC, AND TARTARIC ACIDS, CRITICALLY EXAMINED AND INTERPRETED FROM THE STAND-POINT OF THE "TYPO-NUCLEUS" THEORY.

By OTTO RICHTER, Ph.D.

AMONG the leading combinations of organic chemistry, the family group comprising the water-salts of succinic, malic, and tartaric acids has always been regarded with special and absorbing interest, not only on account of the vast multitude and diversity of substitution-products and derivatives which these water-salts are capable of furnishing, but more emphatically on account of the deep import and significance which all these bodies are felt to possess in a theoretical point of view. With a well-stocked magazine of precious materials at their disposal, our modern speculators have certainly not been sparing in their efforts to unravel the genetic relations and molecular structure of this particular class of molecules. I, for my part, having, years ago, become convinced of the utter futility of these efforts, so long as they continue to be based upon the more or less crude and deceptive principles of the dominant school philosophy, and sincerely believing that my own speculations on this subject are calculated to throw a brighter and purer light upon this intricate, but all-important question, I have thought it my duty to embody the main results of my researches in the present communication. For this purpose I have drawn up the following programme, which consists of three parts. In the first part I shall expound the molecular changes that accompany the natural production of the water-salts of succinic, malic, and tartaric acids in the living organism. In the second part I shall describe the various metamorphoses which these water-salts are prone to experience under the influence of heat and oxidising agents. In the third, and last part, I shall elucidate the molecular changes that attend the artificial production of these water-salts in our laboratories.

Having now acquainted the reader with the leading topics of my programme, I shall at once proceed to direct his attention to those weighty and important matters which form the subject of the first part.

PART I.

On the Principal Molecular Changes that accompany the Natural Production of the Water-Salts of Succinic, Malic, and Tartaric Acids in the Living Organism.

The proper treatment of this question demands that I should enter first of all upon a minute analysis of the chemical origin and mode of formation of the so-called polyatomic alcohols. Apart from the well-established fact that genuine specimens of this type can be formed artificially by subjecting the corresponding hydrocarbons to the action of chlorine, and displacing the directly-absorbed chlorine molecules by an equivalent number of hydroxyl molecules, the more recent experiments of Berthelot and others, devised with the object of studying the effects of oxidising agents upon the free hydrocarbons, tend to the conclusion that these substances are produced in the living organism by the action of atmospheric oxygen upon certain kinds of native hydrocarbons, with which the juices of plants and vegetables are always more or less impregnated. Taking this for granted, and confining my remarks to that variety of hydrocarbons which are called "olefines," and whose chemical constitution is expressed

in my system by the general formula $2H_{2m}C_{am}$ ($m=1, 2, 3$, &c.), I shall yet venture one step farther by maintaining that the said alcohols are the true parent molecules to that particular class of combinations which claims the three acids of the text for its most familiar and most thoroughly investigated representatives.

Now I have good reason for believing that organic acids, which are descended from an olefine-begotten polyatomic alcohol, are produced in Nature's laboratory by a method which, in its general outline, may be roughly described as a process of slow and gradual combustion, in the course of which a certain number of the constituent formylic alcohols (*vide infra*) are made to pass from the category of genuine alcohols into the category of genuine acids, while the alcohol rest re-enters into chemical union with these freshly-formed acids under the typical form of a more or less complex halogen adjunct. According to this view, every olefine-begotten polyatomic alcohol contains within its sphere and substance the germs for the generation of an organic family group whose heterologous members, however widely they may differ from each other in chemical composition and properties, have this important point in common, that they contain the same equivalent number of carbon molecules as the alcohol from which they are descended. The theoretical significance of this rule will be more fully understood in the sequel, where I hope to furnish convincing proof that the three organic acids before us stand to each other in the relation of true heterologues, and that the so-called erythrit, which is a species of saccharine matter endowed with all the characteristic properties of a tetratomic alcohol, has strong claims to its being regarded as their natural and legitimate progenitor. In order to elucidate the precise nature of these curious, but, as yet, very imperfectly deciphered family relations, I shall require to inaugurate the discussion by a description of the molecular changes which accompany the aforementioned process of slow and gradual combustion from one stage of the process to the other.

The first effects of the action of oxygen on a given olefine are supposed to be of a purely catalytic character, and to consist in the conversion of the hydrocarbon from its primitive or normal state of existence into one of its possible isomeric modifications. In this altered form the hydrogen and carbon constituents have re-arranged themselves in accordance with the formula*—

which implies that 2 molecules of hydrogen have become detached and typically changed into acid hydrogen nuclei, and, further, that one of these nuclei has re-united as principal with the rest of the hydrocarbon, which, relatively to that principal, is now destined to play the part of an adjunct, while the other, by appropriating 2 carbon molecules from the said adjunct, has given rise to a formen-holding hydrogen nucleus, $2C_2; H_2$, where the hydrogen and carbon are likewise destined to discharge the relative functions of principal and adjunct. Thanks to their freshly-acquired dissimilar electro-polar energies, these two differently modified hydrogen nuclei are now in a fit and proper condition for chemically combining with each other so as to produce the aforesaid complex molecule, whose first hydrocarbon adjunct is therefore composed of an olefine differing by $2H_2C_2$ from the parent hydrocarbon, while the second adjunct consists invariably of a molecule of formen.

It is here necessary for me to inform the reader that, by

* The reader will bear in mind that the various marks of punctuation used in my formulæ are typical symbols of molecular grouping. Thus, a dot connects the base with its acid; a semicolon connects the hydrocarbon adjunct with its principal; an inverted semicolon connects the halogen adjunct (which includes every species of mono- or poly-normal acids, bases, or salts) with its principal; and a colon connects two or more simple hydrocarbons with one another. Observe, also, that in my rational formulæ the non-essential constituents are generally separated from the essential constituents by a horizontal line, and that the empirical formulæ used in my system are exactly the double of the ordinary formulæ: $H_2=2$; $C_2=12$; $N_2=14$; $O_2=16$.

my fundamental law of meta-chemical order of grouping, which presides over the collocation of the component groups of the molecules, the olefine-holding hydrogen nucleus stands lower in that order than the formen-holding hydrogen nucleus. Moreover, while both these hydrogen nuclei are held to play relatively to each other the part of co-ordinate principals, the former, from being more electro-positive, is understood to occupy in the system an inferior and more central position, in consequence whereof the first of these differently modified hydrogen nuclei is predestined to furnish the stronger, because more electro-positive, ether base, which, by the law of elective affinity, in the sense I take it, is pre-disposed to take possession of the stronger, because more electro-negative, acid.

In order to express these hitherto obscure and undefined relations in technical language, I shall retain the term "principal" for the lower-ranking hydrogen nucleus, and apply the term "ally," to the higher-ranking hydrogen nucleus, allowing a further distinction between the first, second, third, &c., ally in all those cases where, as I shall presently show, the continued action of oxygen on the first hydrocarbon adjunct tends to the formation of two, three, or more formylic ether molecules.

From the preceding remarks the reader cannot fail to perceive that, so far as it goes, my theory of the chemical constitution of the olefine-begotten polyatomic alcohols is not only exceedingly plain and transparent, but that it is susceptible likewise of a high degree of expansion and development. This theory is based upon an original conception, which, in its widest acceptance, may be briefly enunciated as follows:—"So long as a given hydrocarbon preserves its primitive or normal form of molecular arrangement, and which is characterised amongst others by the typical identity in the mode of aggregation of its more or less condensed hydrogen and carbon constituents, the whole system may be said to exist potentially in a state of chemical passivity, whereas, after merging into one of its possible isomeric modifications—that is, when a certain number of its component hydrogen or carbon molecules have assumed the acid-nucleus form of arrangement—this now typically altered system may be said to exist potentially in a state of chemical activity, because it has now acquired the faculty of entering into direct chemical union with oxygen and other metallic or non-metallic elements, for which these acid nuclei present in their respective envelopes a firm and solid point of attachment."

In obedience to this all-important law, the first and immediate product of the direct union of oxygen with a given olefine will be the biatomic ether molecule—

which, in the presence of water, will speedily combine with 2 molecules of that element, with production of the biatomic alcohol—

Accordingly, this latter formula may be taken to express the chemical constitution of the "glycols," among which ethylen-glycol—

stands first in the series.

Let us, in the next place, contemplate the molecular changes which accompany the continued action of oxygen on the end-product of the preceding metamorphosis. These changes I believe to consist in the further abstraction of 2 molecules of hydrogen from the olefine adjunct, and their conversion into 2 molecules of water. At this point, two alternatives present themselves for consideration. These water molecules may either be set at liberty, or, by appropriating a molecule of formen from the olefine rest, they may become re-employed in the construction of a triatomic alcohol, which will then be com-

posed of one olefine-holding principal and two formen-holding allies. Obviously the former alternative, which exercises no modifying influence over the biatomic character of the new compound, ought to give rise to the molecule—

while the latter alternative, which imparts triatomic properties to the new compound, ought to give rise to the molecule—

Accordingly, the first formula may be taken to express the chemical constitution of the "deglycols," among which deethylen-glycol—

stands first in the series, while the second formula may be taken to express the chemical constitution of the "glycerols," among which propylen-glycerol (glycerin)—

stands first in the series.

Let us once more contemplate the molecular changes which accompany the continued action of oxygen on the end-product of the preceding metamorphosis. It is clear that this action ought to give birth, on the one hand to a dehydrogenated triatomic alcohol—

and on the other hand to a tetraatomic alcohol—

which will be composed of one olefine-holding principal and three formen-holding allies. Accordingly, the first formula may be taken to express the chemical constitution of the "deglycerols," among which depropylen-glycerol—

stands first in the series; while the second formula may be taken to express the chemical constitution of the "erythrols," among which butylen-erythrol—

stands first in the series.

It is of importance to point out that my peculiar mode of reasoning, which it is needless to pursue any farther, has actually brought us face to face with the identical alcohol which, as already observed, claims to be regarded as the true progenitor of the three organic acids that form the subject of this paper. Having, therefore, adopted the last-mentioned formula as a safe and trustworthy basis of reasoning, I have founded thereon what seems to be a perfectly rational, harmonious, and comprehensive theory, concerning which I make bold to affirm that it brings to light the true genetic relations and molecular architecture of that almost overwhelming mass of substitution-products and derivatives, among which our triad of acid heterologues has long been conspicuous as the starting-point for an extensive series of highly interesting and instructive experiments.

It was stated above, as one of two possible alternatives, that, under the stimulus of oxygen, the olefine-begotten polyatomic alcohols are disposed to surrender to that element two of their constituent hydrogen molecules, which are immediately eliminated in the form of water. Now I have good grounds for believing that the residual

de-alcohols, as I will shortly call this class of compounds, are very prone to merge into an isomeric modification, where they become endowed with the same feeble acid properties, together with the power of precipitating silver from its salts, which characterise the aldehyds of the mono-atomic system. According to this view, the butylen-erythrol becomes first of all converted into the debutylen-erythrol—

which, by the conversion of the third formylic alcohol ally into the isomeric formite of water, soon changes into the aldehyd-like butylen-erythrite—

and thence, by the absorption of 2 molecules of oxygen, into the butylen-erythrate of water—

In the next stage, the monobasic butylen-erythrate is made to merge into the isomeric modification of the bibasic butylen-meta-erythrite*—

the metamorphosis being accomplished by the second formen-holding ally of the colligated depropylen-glycerol changing into the isomeric formite of water, the formous acid constituent of which is now made to play the part of *principal*, while the formic acid constituent exchanges its function of principal for that of *ally*. In the last stage, the meta-erythrite resolves itself into 2 molecules of water, and the meta-erythrous anhydride—

which, by the method of orthogenesis (Part II., c. i., 3), becomes finally transformed into ortho-erythrite, or ordinary succinate of water—

The reader cannot fail to perceive that, in order to explain the natural production of the malate and tartrate, it is only necessary to suppose that the meta-erythrite of water has become further oxidised, first into the meta-erythrite—

and subsequently into the meta-erythrate—

and that these compounds have then experienced a series of molecular changes precisely similar to those I have just shown to accompany the conversion of the meta-erythrite into the ordinary succinate.

In glancing at the formula of this latter compound, we might be led to imagine that it belongs to the class of readily-oxidisable aldehyds, and consequently that it should be possible to obtain therefrom, by direct oxidation, the ortho-malate and ortho-tartrate, which, by their respective formulæ—

* Let it be borne in mind that, in my theory, all those organic combinations are understood to belong to the class of polybasic meta water-salts, which, besides containing for their halogen adjunct a mono- or poly-atomic de-alcohol, include among their acid constituents two molecules at the least that are moulded on the formyl type. Again, all those organic combinations are understood to belong to the class of polybasic ortho water-salts, which, besides containing for their halogen adjunct a mono- or poly-atomic de-alcohol, include among their acid constituents not a single molecule, or, at the most, one only, that is moulded on the formyl type, while the rest are all moulded on the oxalyl type.

and—

are at once recognised as the two nearest upper heterologues of the succinate, these formulæ being at the same time well adapted to illustrate the all-important law that the oxidation always progresses from right to left, in the present instance from the side of the oxalous acid ally towards the side of the oxalous acid principal. Yet, strange to say, all attempts to oxidise the succinate by direct methods have invariably proved a failure.

In pondering the probable cause of this discrepancy, I could not help being struck with the scarcely fortuitous circumstance that in my system the true aldehyds are all constructed on the formyl type, with an uneven hydrocarbon for their adjunct, whereas the succinate and its homologues are all constructed on the oxalyl type, with a mono- or poly-atomic de-alcohol for their adjunct. Now, it is perfectly conceivable that these typical differences are of a nature to exercise a certain modifying influence upon the intensity of attractive force, which the carbon nuclei of these two kinds of acids are capable of concentrating upon a contiguous molecule of oxygen. But, while I shall be glad to learn that within the precincts of one of our laboratories this problem of direct oxidation has at length received a practical and commercially-profitable solution, I am strongly impressed with the notion that in the living organism this metamorphosis is accomplished by a different and presumably far more feasible method.

This method I hold to consist in the previous conversion of the ortho-succinate into the isomeric modification of the meta-succinate—

which, on the hypothesis that its complex carbon adjunct is capable of assuming two typically-distinct forms of grouping, is here represented as occurring in an α and β variety.

According to my view, the two acid constituents being now moulded on the formyl type, become thereby capacitated to impart to the meta-succinate the chemical character and properties of a true aldehyd, which, by the accession of one pair of oxygen molecules to the formous acid principal will give rise to the meta-malate, and, by the accession of a second pair of oxygen molecules to the formic acid ally, will give rise to the meta-tartrate, whence the ortho-malate and ortho-tartrate will then be finally produced by the method of orthogenesis, for which the reader has already been referred to the second part of this paper.

Having now briefly delineated the main features of those natural processes, whereby the three acid heterologues of the erythric family group are supposed to be engendered in the interior of plants and vegetables, I shall proceed to the second part of my programme, for which I have reserved the disclosure of a new set of molecular relations and modes of grouping, the theoretical importance of which can scarcely be over-estimated.

(To be continued.)

CALORIMETRIC PYROMETER FOR THE DETERMINATION OF HIGH TEMPERATURES.

THE problem of the determination of temperatures higher than that of the boiling-point of mercury has not been solved in a satisfactory manner. M. J. Salleron describes in *Les Mondes** an instrument which, founded on the principle of the calorimeter, he thinks unites the best approximative conditions with practical simplicity. The instrument consists of a cylindrical vase of red copper open at its upper end, and surrounded by an outer

* Vol. xxxi., No. 13.

envelope of brass. The red copper vase is supported in this outer vessel by means of an annular disc of wood. A layer of air thus separates the two vessels, and this arrangement has for its end the diminishing of the loss of heat by radiation and also by conduction. For the same reason, the mouth of the vase is closed by a wooden cover pierced with an opening. By this opening, there are introduced into the calorimeter determined weights of water, and a heated mass of red copper. This piece of copper (in the shape of a bolt) rests on an arm passing through the wooden cover, and the arm is susceptible of such movement as will enable the operator to agitate, and with the hot copper bolt equally heat, the liquid in the vase. The heat of the liquid is determined by means of a thermometer.

To use the apparatus, half a litre of water is measured into the copper vase, and its initial temperature, t , noted by means of the thermometer. The cylinder of red copper (which weighs 106 grms.) is placed in the furnace of which it is desired to ascertain the temperature, T , and, when heated, is rapidly immersed in the water of the calorimeter. The water is agitated until equally heated; and, during this time, the mercury of the thermometer first rises rapidly, then more slowly, and finally becomes for a few instants stationary before it commences to fall. The final maximum temperature, t' , is noted, and the temperature, T , found by the formula $T = 50(t' - t) + t$. Thus, if before the immersion of the copper cylinder the temperature were 15° , and afterwards 25° , the temperature of the heating source would approximate—

$$[50(25 - 15) + 25 = 525].$$

Platinum may be substituted for copper for temperatures above 1000° .

The method supposes that, at the instant of its immersion, the copper or platinum cylinder possesses exactly the temperature to be measured. To realise this condition, it is necessary to take precaution against loss of heat during its transport to the calorimeter. With this view, M. Salleron introduces the copper cylinder into an iron tube, provided at one extremity with a wooden handle, and at the other with an opening only sufficiently large to admit of the passage of the cylinder. This opening is excentric with relation to the axis of the tube, so that the weight introduced into the tube is maintained there when the tube is held in one direction, and will fall out when the tube is turned half round in the other direction. A copper cylinder is introduced into the tube, and this into the source of heat until the copper is raised to a temperature uniform with the source of heat, when the tube is removed, quickly carried to the calorimeter, and, by a half-turn, the copper cylinder is thrown into the water. The heat of the iron tube practically prevents radiation from the copper cylinder.

ON THE ENERGIES OF THE IMPONDERABLES, WITH ESPECIAL REFERENCE TO THE MEASUREMENT AND UTILISATION OF THEM.*

By the Rev. ARTHUR RIGG, M.A.

(Continued from p. 69).

To return, then, to Kater's experiments. He had first to determine a pendulum which should vibrate seconds in the latitude of London. He did it in the house of Mr. Brown, in Portland Place, which house has an astronomical bearing from Portland Chapel of 74° deg. 38 min. 50 sec. west from north, the distance being 283 feet, and therefore the house is about half-way up Portland Place on the left-hand side. In that house the pendulum was first adjusted. Nothing seems easier than to deal with a simple vibrating ball on a string. It is not, however, so easy as it seems. It can

not be made to swing in the same plane as this one now appears to do. If left free to choose its plane of vibration it is seldom contented. It will not have a dozen swings in the same plane; it must, therefore, somehow or other, be made rigid, and so prevented from such vagaries. Here is a small vessel of lead, hanging by a bundle of untwisted fibres from a hook, and you might think nothing could be easier than to let it swing backwards and forwards on the same path, but it will not swing for two minutes in the same path; hence, pendulums are all compelled to act in restrained paths, and generally supported on knife edges. French clocks have two strings of silk to the pendulum. These are fastened to two hooks at the top, and the pendulum rod being hung from the junction of the two silken cords, it is constrained to describe a path in a plane at right angles to that in which are the silk threads.

To return to the leaden vessel. It is now filled with fine white sand, and at the bottom there is an opening out of which the sand can trickle whilst the vessel swings freely. The figure caused by the sand falling on a board beneath will show the path that the vibrating body describes. It shall now be let go in what appears to be a straight line. If you watch that path you will see it is a very curious one. The sand at once indicates that the ends of the line are travelling round, also that the line itself is becoming wide in the middle. In fact a straight line is seldom formed by the falling sand from such pendulums. Even if a circular path be commenced, you will find it cannot be retained. It reminds one very much of one of the secular astronomical changes, that is, our year of 365 days and a fraction results from this gradual advance of the perihelion path of the orbit of the earth; observe it tends first to a straight line, then through an ellipse to a circle, and then a return action commences, and it will repeat this process from the straight line opening out again, and so pass on through various phases, until it comes to rest. Hence a pendulum constructed of a simple form is of no value, and yet it is in its simple form we require it. It was useful to assume for the purpose of the calculation that we can make a pendulum do that which this swinging vessel of sand is not doing.

Captain Kater was the first to deal with the case of converting the compound pendulum into a simple one. A pendulum is said to be a simple one when it consists of a heavy particle at the end of a very light thread. Such is almost an imaginary pendulum. All pendulums that we see are compound ones. Now, by pursuing the plan adopted by Captain Kater, he was able to obtain from the compound pendulum what would be the length of an equivalent simple pendulum. His pendulum has two pairs of knife-edges, a pair at the upper end, on which it swings, and a pair at the lower end. He placed one pair of these knife-edges on a smooth, hard surface, so that the pendulum might vibrate without anything causing it to continue its vibrations except the force of gravity. Now, if you look to this diagram, you will see the motions of a compound pendulum. If it were short it would move thus, and if it were longer it would move more slowly. The black dots in the diagram represent the lower ends of pendulums of different lengths. Assume that the black dots are the ends of separate pendulums, one behind the other, from the same support, they will then occupy those places after the same interval of time from rest; if, however, these pendulums are united, then the one is kept back by the action of the other; now they are really united in a compound pendulum. There is, however, some point or other at which, if all these masses were concentrated, the velocity at that point would be the velocity of the mass, therefore such a pendulum would vibrate in the same time, and it would be called a simple pendulum. Kater found that this collected point, which is called the centre of oscillation, and this at which the pendulum is suspended, are interchange-

* The Cantor Lectures, delivered before the Society of Arts.

able; in fact, he found that if the pendulum was accurately adjusted by means of these movable weights, he could suspend it upon a pair of the knife-edges, and he could get a certain number of vibrations in a minute or a second. Then, if he turned it upside down, assuming the pendulum to be right, and caused it to swing as before, upon the other pair of knife edges, it would make the same number of vibrations. Those two points he marked, and the distance between them is the length of an equivalent simple pendulum. With such a compound pendulum as now described, and of which the one before you is a copy, counting the number of vibrations it makes, you can always deduce the length of a simple pendulum that would make the same number of vibrations.

What Kater did, then, was this—he had a clock kept going, strictly to truth, that is, to true astronomical time. The clock was furnished with a gridiron pendulum of the construction shown in the diagram, and so carefully arranged as not to be altered in length in consequence of change of temperature. On the bob of the pendulum, in front, was a white speck, as on the pendulum bob of this clock. He placed the compound gravity pendulum, which has been described, in front of the clock, the clock pendulum beating 86,400 strokes per mean solar day. The rate of the clock was determined by astronomical observations, and therefore, on any part of the earth's surface, it would be possible to so arrange the solar pendulum that the clock should always record 86,400 beats in a mean solar day.

Now let us turn to this two-ended pendulum of Capt. Kater. It is of an invariable length, and acted upon directly by the force of gravity; there are no weights or clockwork in connection with it. When it is up on one side, it is the power of gravity that causes it to fall, and it is gravity which keeps it going. If, for example, a powerful magnet be placed under that pendulum, then it will come to rest sooner than it would otherwise do, because it is pulled down with greater force. If, therefore, gravity changes in its pull on this pendulum, it will tell on the rate of its vibrations. The rate of vibration of the equivalent simple pendulum is known, because it has been calculated from this compound one; hence, if this compound pendulum be placed in front of the clock keeping astronomical time, and if the vibrations of the pendulum be counted whilst the vibrations of the clock pendulum are being recorded, it might be ascertained whether the force of gravity varied in different places.

The means by which Kater compared these vibrations are very simple. You see the white speck, previously referred to, on the bob of this gridiron pendulum. He took a telescope, and placed it at some distance on a level with that white speck. Between the white speck and the telescope, and near to the gridiron pendulum, swung the gravity pendulum, which moved slower than the other, being made a little longer. Keeping his eye upon the telescope, and directed upon a narrow piece at the end of the gravity pendulum, which was the same width as the white circular speck upon the bob of the clock pendulum, he could tell when the two coincided. As one pendulum swung slower than the other, it was quite clear that a coincidence must take place, and he noted the time of the coincidence. That was the beginning of counting vibrations, and he then waited until they separated, and until the coincidence again took place a second time, which gave the number of the vibrations in a given time as recorded by the clock. Experiments like these were repeated very frequently and carefully, until at length the average was obtained as to the number of vibrations that this gravity pendulum made, compared with the vibration that the one on this mean solar clock made. Within the tube of this telescope there are crossings of very fine wires—so fine as to be hardly visible to unaided vision; the threads of a spider's web were formerly used for this purpose. A spider is taken in the fingers; then, if shaken,

he would run his web out to save himself, and this web was placed in the focus of the eye-piece, and the threads were so that the crossing of them was in the axial line of the telescope. It was by looking along that axial line that the time was observed when the coincidence of these two pendulum marks took place. The accuracy with which that was done is more easily to be imagined than realised.

Assuming that this has been accomplished, let us look for a moment to other elements which would disturb the result. In the first place, the pendulum vibrated in air; and you were told, in the first lecture, that a body weighed in air and weighed in any other medium is not balanced by the same weight. Hence, the effect of the air upon the pendulum has to be considered. Then the pendulum is vibrating in a changing atmosphere, sometimes warm, sometimes cold, and a change of the temperature causes an expansion or contraction, hence the effect of that expansion was to be considered. And, simple as it seems, to estimate whether a pendulum is longer or shorter is really very difficult. Indeed, great was Captain Kater's perplexity about it.

He measured the length of his pendulum thus:—He formed a box similar to the one on the table, and laid his pendulum in it, and applied a microscope over one of each pair of opposite knife-edges, placing behind them a piece of white paper, so that the edge might be seen. He then applied the microscope. Again, he put beneath them a piece of black paper, and he found that the measurement with the white paper was never the same as the measurement with the black paper. After describing how with microscopes he attempted to measure between knife-edge and knife-edge, by placing them when white on a black ground, and when black on a white ground, he adds:—"In one case, the knife-edges seemed to start forward to each other." This difficulty is summed up thus:—"On the cause of this extraordinary fact I can hazard no conjecture, and it remains an interesting subject for future investigation."

We now know that this resulted from a phenomenon called "irradiation." Hence he was bound, even in looking through those microscopes to strike an average of the apparent errors.

Another error that occurred, which he also found great difficulty in remedying, and indeed never did remedy, so that in fact the experiments he made are liable to some infinitesimal corrections still, was this:—If a pendulum vibrates, as this one was doing just now, the air clings to it, and is carried along with it, from what is called the "viscosity" of the air. That viscosity is such that, if you were to put a short piece of gold-leaf projecting edgewise upon the face of the pendulum bob, you would find that the gold-leaf moved with the action of the pendulum, and was carried along with it, so that it turned neither to one side nor the other. If, however, the gold-leaf projected beyond a certain distance, then you would find it bend with the air. Therefore, the atmosphere in immediate contact with the bob was dragged along with the pendulum, and that particular element Captain Kater was not aware of. Government, some years ago, in order to set this question at rest, had large vacuum chambers erected, and pendulums set vibrating in them, to ascertain how great an error was caused by the viscosity of the air.

Captain Kater having determined the length of this pendulum in the latitude of London in 1818, it was thought of great consequence to ascertain how far the force of gravity varied in different latitudes.

A memorial was presented to the Government in 1818, in order to ascertain by means of a pendulum how gravity varied throughout the British Isles, and Kater was commissioned to take steps for the purpose. Government placed at his disposal certain members of the Royal Corps of Engineers, with whom he set out to the north of Scotland, and made experiments at various places. He went up to Unst, in the Shetland Isles, then he came down to Portsoy, then to Leith, then down to Clifton, in Yorkshire, then --

Ashbury, then to London, and then to the Isle of Wight, and in each of those places he made certain experiments based upon the principles now too briefly described. This lecture would extend far beyond the allotted time if it entered into details with reference to local arrangements and special calculations. It may suffice to refer to the table for particulars of the results. The following is a copy of the table:—

Name of Place.	Latitude of Place.	Vibrations in a Mean Solar Day.	Length of a Pendulum to Vibrate Seconds.
	Deg. Min. Sec.		
Unst	61 45 28.20	86,096.90	39.17146
Portsoy ..	57 40 58.65	86,086.05	39.16159
Leith Fort ..	55 58 40.80	86,079.40	39.15554
Clifton ..	53 27 43.12	86,068.90	39.14600
Ashbury Hill	52 12 55.32	86,065.05	39.14250
London ..	51 31 8.40	86,061.52	39.13829
Shanklin, or rather Dunmore ..	50 37 23.94	86,058.07	39.13614

From this table it will be seen that the length of a pendulum vibrating seconds in the places respectively entered is that given in the last column.

These lengths are sufficient to enable a mathematician to calculate the force by which the pendulum is caused to swing. Now, as the only force causing this swing is that of gravity, such a calculation determines the force of gravity at that place in relation to its power to produce motion. Hence is deduced those 39 inches, which, in ordinary expression, is thus broadly stated to be the length for pendulums vibrating seconds in the latitude of London. Captain Kater deduced that 39.13829 inches was the length of a pendulum vibrating seconds in Mr. Brown's house in London. This length requires to be reduced to sea-level. Now, the rooms of the Royal Society, at Somerset House, are 81 feet above low-water, and by the aid of a mountain barometer, made by Ramsden, Kater found the room in Portland Place to be 2 feet below those of the Royal Society, and, as the length of pendulum above the floor was 4 feet, the elevation of pendulum above sea-level is 83 feet.* Now, gravity varies inversely as the square of the distance of the place from the centre of the earth; therefore, the length of pendulum must be increased in this proportion; and, taking the radius of the earth for the latitude of Portland Place to be 3954.583 miles, we have 39.1386 inches for pendulum vibrating seconds at the level of the sea in the latitude of London.

The greatest difference between the mean and that of any of the sets of experiments is only 0.00028 of an inch, or 1/144,000 of length of pendulum. The length 39.1386, as thus determined, is that required to perform one vibration, in 86,100 of a mean solar day, under the circumstances described, and at the level of the sea.

Finding how much could be obtained from this with regard to the British Isles, Government commissioned Captain Sabine to go to different places on the east coast of Africa, the Island of Ascension, Bahia, Trinidad, Jamaica, New York, Greenland, and Hammersfest, in Norway, and repeat Captain Kater's experiments. These experiments are repeated, and then, by an arithmetical process which need not be referred to in detail, it was very easy, having given the number of vibrations of this invariable pendulum (for the distance between these knife-edges did not vary) performed in a solar day, to calculate the power that was pulling it; and from that calculated power could be obtained the mass of the earth beneath the place where it was being pulled, making, of course, all the allowances for corrections and other circumstances. That calculated power gives the 32 feet which we are all acquainted with as the measurement of gravity. The meaning of which is, that gravity will generate in a 1-lb. weight, in one second, a velocity thirty-two times greater than that which it is agreed shall be called

* There is reason to conclude that these measurements require to be corrected.—A. R.

the unit or absolute measure of force. Put conversely, the absolute unit of force is equal to the weight of 16 ozs.

$32 \cdot 2 = \frac{1}{2}$ oz. nearly.

Captain Foster afterwards repeated these experiments, and made others, and from them has been obtained the figure of the earth, and calculations of all kinds used in scientific investigations throughout the globe depend upon them. Captain Foster was unfortunately drowned in the river whilst observing some of his experiments, but Mr. Baily undertook to tabulate his results, and completed the calculations on the data which had been obtained by Captain Foster's observations. The calculations Mr. Baily made for this purpose occupy many closely-printed quarto pages of figures. The result was solely to ascertain the length of the pendulum, and so deduce the figure of the earth. Great beyond all ordinary estimate is the amount of care, patience, perseverance, and anxiety that attends experiments of this kind.

(To be continued.)

NOTICES OF BOOKS.

Plattner's Manual of Qualitative and Quantitative Analysis with the Blowpipe. From the last German edition, revised and enlarged. By Prof. TH. RICHTER, of the Royal Saxon Mining Academy. Translated by HENRY B. CORNWALL, A.M., Assistant in the Columbia College School of Mines, New York, and JOHN H. CASWELL. Second Edition, revised. New York: D. Van Nostrand.

It would be utterly superfluous on our part to express any opinion on a work which has won so high a reputation as the great masterpiece of the late illustrious Professor of Freyberg. The present version is founded on the latest German edition, enriched with the valuable additions of Professor Richter. Among the improvements we notice the introduction of no fewer than 150 new minerals, a quantitative test for mercury, the description of new apparatus for measuring silver assay buttons; and an elaborate index in three divisions—one for minerals, another for metallurgical products, and the third general. The instructions for the quantitative determination of bismuth, cobalt, nickel, iron, and for the examination of coal, have also been added since the appearance of the former English translation from the pen of the late Dr. Sheridan Muspratt. The reader will be enabled to compare the two versions when we state that Dr. Muspratt's has only 392 pages exclusive of index, while Mr. Cornwall's extends to 522, and is more compactly printed. The editor appears to have carefully and conscientiously discharged his duties. The retention of the old Berzelian formulæ, in which oxygen is expressed by dots, and sulphur by commas placed above the symbols of the other elements, may seem strange to some readers, but it is not without advantages in mineralogical matters. We cannot in passing refrain from protesting against an expression which has caught our attention. To be told that—"copper occurs quite extensively in nature," grates on the ears of all who have been accustomed to precision of thought and language. As the latest and best English version of Plattner this book will be indispensable to all students of mineral chemistry and its applications.

Observations on the Agricultural Chemistry of the Sugar-Cane. By T. L. PHIPSON, Ph.D., F.C.S. London: Ranken and Co.

WHAT may be called the stereotyped orthodoxy of agricultural chemistry receives from time to time very severe shocks. But a few years ago we were taught that the sole duty of the chemical manure maker was to offer his customers abundance of phosphoric acid in a soluble form, and of nitrogen—though the importance of the latter was

not universally conceded. Now we learn alike from scientific research and from practical experience that a plot of land may become exhausted of other constituents as well as of phosphates and combined nitrogen, and that in such cases superphosphates and ammoniacal salts are useless. This truth is ably enforced by Dr. Phipson, not merely as regards the sugar-cane, but for crops in general. He points out that the substances added to a soil must not only be sufficient in quantity and right in kind, but must also be in an assimilable condition if the plants are to be benefitted. Liebig showed that by burning a plant to ashes, and analysing the result, we learn the food necessary to render it luxuriant in a given soil. But if we burn a quantity of wheat-plants to ashes, and apply this residue as manure to a fresh plot of land sown with wheat, the crop proves a failure. The author states—"The burning of a vegetable to procure the ash renders the mineral food it naturally contains almost useless as manure." On superphosphate employed as a sugar-cane manure he places little reliance. Ammoniacal salts have been largely tried in Demerara; the result being the rapid growth of the canes, and the production of a juice poor in sugar. A very important fact to which the author calls attention is that the analyses of the mineral ingredients of plants, incinerated after they arrive at maturity, must coincide, and "can alone teach us accurately what any plant takes from the soil." Dr. Phipson was once called to report upon a number of analyses of sugar-cane, executed by chemists of admitted skill, but which nevertheless presented serious discrepancies. After a long investigation he found that the samples of cane had been taken at various stages of growth, and the results consequently could not coincide. On the other hand, an analysis of some ripe coffee berries from Ceylon coincided most closely with one made thirty years ago with West-Indian coffee. This is an apt illustration of the old, but not stale, truth that analyses of organic substances except made under distinctly defined circumstances are merely a waste of time. The author finds that the sugar-cane withdraws lime from the soil more rapidly than magnesia. Hence, "the degree of exhaustion which a cane soil has undergone can, to a great extent, be ascertained by comparing the relative amounts of lime and magnesia" found on analysis. The deficiency of humus—an article not long ago proclaimed of little value—is found in Java to be a source of sterility, "by causing a want of porosity, of nitrogen, and of carbonic acid." In this country every nurseryman and market gardener knows the importance of humus, however unable he may be to point out its exact mode of action. The most important portion of Dr. Phipson's pamphlet is where he shows the value of farmyard manure, night-soil, and similar residues as containing not merely "all that the plant requires," but also "in the proper state for assimilation." This truth has of late been forcing itself, from various points of view, upon the attention of agricultural chemists. Manures made from excrementitious and sewage matters, though poor in the two fashionable items of phosphoric acid and ammonia, are yet found in practice to give better results than some which "analyse well." Dr. Phipson's pamphlet is, in short, highly suggestive, and whilst we cannot approve of all it contains—e.g., the laudatory mention of certain firms in the manure trade—we have much pleasure in recommending it to our readers.

The Retrospect of Medicine. Edited by W. BRAITHWAITE, M.D., and JAMES BRAITHWAITE, M.D. Vol. lxvii., Jan. to June, 1873. London: Simpkin, Marshall, and Co.

THIS volume, subdivided into sections on practical medicine, surgery, midwifery, &c., contains little matter directly connected with chemical science. We notice certain particulars on a recent outbreak of enteric fever at Nunney, in Somersetshire. The disease is distinctly

shown to have been introduced by the evacuations of an individual attacked finding their way into a small stream which supplied the village with water. With the introduction of a supply of uncontaminated water the number of fresh cases fell, from eight to thirteen weekly, to five; and in the subsequent week to one. Dr. B. W. Richardson gives an account of his last new anæsthetic methylen ether, which he considers safer than chloroform or methylen bichloride, whilst possessing all their advantages. That vexed question—the therapeutic use of electricity—is also discussed at some length.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Under this heading will be found an encyclopedic list of chemical papers published abroad during the past week, with abstracts of all susceptible of advantageous abridgment. The two half-yearly volumes of the CHEMICAL NEWS, with their copious indices, will, therefore, be equivalent to an English edition of the "Jahresberichte."

NOTE. All degrees of temperature are Centigrade, unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances de l'Académie des Sciences, July 21, 1873.

Third Notice on Guano.—M. Chevreul.—The author examines into the cause of the development of carbonic acid gas when the hard portions of the guano come in contact with water, and announces his intention of examining under what circumstances carbonate of ammonia behaves in this manner.

On Nitrification in Soils.—M. Th. Schlösing.—The author finds that the quantity of nitric acid produced is not proportional to the amount of oxygen contained in the air, the relation between these two quantities—the amount of nitric acid produced, and the proportion of oxygen contained in the air, being very complicated. When the proportion of oxygen in the air does not exceed $\frac{1}{4}$ per cent, the amount of nitric acid produced is even then very considerable. The arable soils almost entirely separate the oxygen from the other gases present in the atmosphere. As the proportion of oxygen augments the yield of nitric acid is increased, and seems to attain its maximum when the oxygen is about 16 per cent; beyond which it decreases in proportion to the increase of the oxygen. These experiments seem to prove that the free nitrogen and oxygen of the air take a direct part in the formation of nitrates. The soil used by the author in his experiments was rich in humus and in lime. All carbonic acid and ammonia pre-existing in the atmospheres operated upon had been previously eliminated.

On a Compound of Picric Acid and Anhydrous Acetic Acid.—D. Tommasi and H. David.—The formula of the new compound is—

It may be regarded as a picrate in which 1 atom of metal is replaced by acetyl. It melts between 75° and 76° , begins to decompose at 120° , turns brown at 180° , and is completely decomposed at 260° , leaving a carbonaceous residue. Alkaline solutions split it up in the cold into acetic and picric acids. It does not detonate on percussion, but if mixed with chlorate of potassa it explodes with violence.

Action of Pyrogalllic Acid upon Iodic Acid.—M. Jacquemin.—Pyrogalllic acid placed in contact with iodates turns brown instantly. The reaction is the same whether the iodic acid be free or combined. Bromic and chloric acids have no such action, except the latter is concentrated enough to ignite paper; whilst iodic acid acts energetically even when diluted with 250 parts of water. Hence, pyro-

gallic acid may serve as a reagent to indicate the presence of iodates occurring as impurities in a commercial sample of iodide of potassium.

On a Native Compound of Oxides of Iron and Copper, and on the Artificial Formation of Atakamite.—C. Friedel.—This new mineral—delafossite—is found at Katharinenburg, Perm, Russia, accompanying laminary graphite. Its composition is—

Sesquioxide of iron		47.99
Alumina		3.52
Suboxide of copper		47.45

98.96

Its sp. gr. is 5.07; its hardness 2.5. It yields a greyish black powder, and is opaque even in the thinnest laminae. Atakamite was artificially produced by heating a solution of ferric chloride with cuprous oxide to 250° for eighteen hours in a sealed tube. Brilliant green crystals were deposited on the sides of the tube, agreeing in form and properties with atakamite.

On Spontaneous Alterations in Eggs.—U. Gayon.—The author finds that the putrefaction of eggs is correlative with the multiplication of vibrones, and is not in all cases accelerated by shaking and mixing up the white and the yolk. Mouldiness may also set in—which is not to be confounded with putrefaction—and is caused not by bacteria or vibrones, but by vegetable spores. In another and rarer change the egg gives off a peculiar acid smell without putridity, having an acid reaction, and containing alcoholic products. In this case no bacterian germs are present.

Note Concerning the Change of Velocity of Regime in Isochronous Regulators.—M. Y. von Villard.—The author here discusses the case of a temporary change; as where, after observing stars with an equatorial, one wishes to observe a planet, a comet, &c., and it is desirable to be able to alter the instrument quickly. He mounts the axis of the regulator in a movable frame, so that one may give it any inclination to the vertical. He investigates the mode of action of an isochronous regulator with the axis inclined.

New Researches Confirming the Localisation in the Cerebellum of the Co-Ordinating Power of Movements Necessary to Walking, Standing, and Equilibration.—M. Bouilland.—The author has been led to this result by experiments on some thirty animals of different species, and by clinical observation. He doubts Flourens's doctrine that the cerebellum co-ordinates all the voluntary movements of translation and prehension. Further, in place of holding that the brain co-ordinates none of the voluntary movements of translation and prehension, he holds that it co-ordinates a great number of them, but not those of walking and standing.

Direct Demonstration of the Fundamental Principles of Thermo-Dynamics; Laws of Friction and Impact according to this Science.—Continued extract from memoir by M. Lédien.—The writer here establishes some formulæ, and gives some explanations relative to motion and velocity in a system of material points.

Movement of a Spherical Segment on an Inclined Plane.—Extract from memoir by Gen. Didion.

Spectra of Iron and some other Metals.—P. Secchi.—He wished to ascertain whether the line 1474 K, seen in the corona of eclipses really belonged to iron, as has been asserted. Fifty Bunsen couples were used, giving a powerful force. The voltaic arc of iron was got in various ways—(1) With two iron cones; (2) with one at the positive pole, and a carbon cone at the negative; (3) with drops of iron in a little hollow of a carbon point forming positive pole. He used a direct-vision spectroscope, and with a heliostat reflecting the sun's rays between the electric poles he could have the solar spectrum and that of the electric arc superposed. He examined carefully the lines in the superposed spectra, and also those in the

iron spectra alone; also tried various kinds of iron, but in no case did the line in question appear; and he concludes, that if it belongs to iron, it is developed in circumstances of temperature still unknown. He makes some further remarks on the spectrum of the arc from the carbon points which, projected on a white screen with a Duboscq apparatus, had a size of about 10 centimetres, so that its different parts could be well examined separately. He notes some differences from what Morren and others have observed in the carbon vapour spectrum. Experimenting as to whether any other metals gave the finely fluted spectrum of carbon, he found that aluminium gave it admirably.

Permeability of the Sand at Fontainebleau.—M. Belgrand.

Experiments on the Movement of Swell Produced in an Artificial Channel, making the Water Rise on an Inclined Plane to a Height Sensibly Constant.—M. de Caligny.—The writer's design is to show the advantage, for study of waves, of isolating a phenomenon in an artificial channel. The experiments made were of a rough and preliminary character.

Letter from M. Nordenskiöld, from Mossel Bay (lat. 79° 54', N.), where the Expedition passed the Winter.—Among other interesting facts it is stated that Lieut. Parent and Dr. Wykander had been studying the aurora and its spectrum with an excellent apparatus, and had determined seven different spectral lines; which Dr. Wykander thinks are exactly the spectrum of the lower part of the flame of a candle or of a petroleum lamp. This seems to indicate some relation between the aurora and the fall of cosmic dust containing carbon, hydrogen, metallic iron, along with snow (as described in a previous letter). It may explain anomalies observed in auroral spectra in different places and at different times. The vegetation of Algæ seems to attain a maximum in the darkness and cold of an Arctic winter. The botanist considers they can live without light, and at a temperature of -2° C. The photographer found that a sensitised plate kept twelve hours on the sea bottom, where Algæ were flourishing, underwent no change. In walking along near the coast one observes a bright luminous trace on the snow. This is produced by myriads of small crustacea at a temperature of -10° C.

On some Matters Suited for the Destruction of Phylloxera.—M. Petit.—These are coal-tar, ammoniacal water, and the lime from gas refineries.

New Spectral Observations which are in Discord with some Theories of Solar Spots.—M. Tacchini.—The author followed the progress of faculae giving a metallic spectrum (and attesting eruption) throughout a whole semi-rotation, but found no spot appear. This, in his view, increases the difficulties of both P. Secchi's and M. Faye's theories. On the former theory every eruption should give a spot; and on the latter a metallic spectrum should only be observable in case of a cyclone, i.e., a solar spot. The present observation proves the contrary. M. Tacchini further states that he had observed in a solar region an eruption extending over nearly 50° of latitude, and not terminating for seven days; during which time magnesium and Kirchhoff's line 1474 were always visible on the entire border of the sun. Here, then, is a general movement in the upper layers of the sun, independent of the movement of rotation.

Researches on Electrical Condensation.—M. Neyreneuf.—The following conclusions are arrived at:—(1) The constancy of charge of the ordinary electrophorus is due to imperfect contact; (2) The employment of a proof plane is quite defective for quantitative and even qualitative researches as to the electrification of an insulating plate; (3) the employment of a gold-leaf electroscope requires great precaution, because of the variable state arising from the action of the insulating plate of a condenser as electrophorus; (4) an electrophorus placed

in the best theoretical conditions would hardly give any effect, because of the antagonism of spontaneous discharges, and those obtained by ordinary action of the apparatus.

Annalen der Chemie und Pharmacie, band clxviii., heft 1.
(Neue Reihe, band xcii., heft 1.)

On Azophenylene.—Prof. A. Claus.—This substance, obtained by the dry distillation of the azobenzoate of lime, consists of—

Carbon	79.12
Hydrogen	5.49
Nitrogen	15.38

99.99

and may be expressed by the formula $C_{12}H_8N_2$. It forms long, light yellow, shining needles, which melt at 170° to 171° and sublime unchanged at higher temperatures. It dissolves in about 50 parts of cold alcohol, but readily in the same liquid when hot. It is very sparingly soluble in water, and crystallises unchanged from these solvents. It is volatilised along with the vapour of boiling water, to which it gives a pleasant aromatic odour resembling that of the oil of cinnamon. In hydrochloric acid it dissolves unchanged and may be re-crystallised from the solution. Nitric acid converts it into a nitro product which separates out in brown, flocculent, crystalline masses. On prolonged heating with concentrated sulphuric acid it is converted into a sulpho acid. The author has formed and examined bromazophenylene, $C_{12}H_8N_2Br_2$, hydrazophenylene, $C_{12}H_{10}N_2$, and the combinations of the latter with sulphuric and hydrochloric acids, and with platinum. The paper concludes with a lengthy hypothetical dissertation.

On Di-Iodhydrin.—Prof. A. Claus.—Di-iodhydrin is a pale yellow thick oil, of the sp. gr. 2.4 at a temperature of 15° . At -16° to 20° it congeals to a colourless crystalline mass. Its formula is $C_3H_6I_2O$.

Action of Ammonia upon Dichlorhydrin.—Prof. A. Claus.—If dichlorhydrin is heated with alcoholic ammonia to 105° in a sealed tube, one of the products is an amorphous gelatinous body—chlorhydrinimid,— $C_{12}H_{27}N_3Cl_2O_4$.

It is a white body, insoluble in water, alcohol, ether, and even in concentrated acids. If the alcoholic ammonia is very weak there are produced—instead of chlorhydrinimid—two new bases, diamidohydrin and glycidamin.

Preparation of Dichlorhydrin.—Prof. A. Claus.—About 800 grms. of glycerine (concentrated till its boiling-point is 195°) are placed in a flask holding 2 litres, and 2 kilos. of chloride of sulphur are gradually added with constant stirring, whilst the whole is heated in a bath of common salt. The flask is fitted up with a cohobation tube, which is removed after the heat has been applied for 7 to 8 hours in order to drive off the sulphurous and hydrochloric acids. When the mass is cool 2 or 3 volumes of ether are added, the deposit of sulphur is filtered off, the ether is distilled off in the water-bath, and the residue submitted to distillation over the open fire. After thrice repeated rectification pure dichlorhydrin is obtained, boiling at 178° .

Applicability of the Periodic Law to the Metals of the Cerium Group.—D. Mendelejeff.—A controversial paper in reply to Rammelsberg. (See *Ber. d. Deut. Chem. Gesells.*, 6, 84.)

Preparation of Ethylen and Ethylen-Bromide.—E. Erlenmeyer and H. Bunt.—This paper would not be intelligible without the accompanying diagram.

Action of Nascent Hydrogen upon the Oil of Bitter Almonds.—Hugo Ammann.—The author examines hydrobenzoin and its behaviour with chloracetyl and chloride of phosphorus; also isohydrobenzoin, which, as well as hydrobenzoin, is formed by the action of sodium

amalgam upon the oil of bitter almonds, and its behaviour with the same reagents.

On Bromised Benzol Sulpho Acids.—Adolph Woel.—This paper gives an account of dibrombenzol-sulpho acid, and its barium, calcium, potassium, ammonium, copper, and lead salts; its behaviour with melting hydrate of potassa; experiments on the preparation of benzol-tricyanide and benzol-tricarboxylic acid; monobrombenzol-sulpho acid and its transformation into benzol-dicarboxylic acid.

Investigations on the Constitution of Piperin, and its "Splitting up" Products, Piperic Acid, and Piperidin.—Rud. Fittig and Ira Remsen.—This paper treats of the synthesis of piperonylic acid, and of a new mode of formation of protocatechuic acid aldehyd.

On Ethylen-Protocatechuic Acid.—Rud. Fittig and Thomas Macalpine.—The formula of this acid was ascertained to be $C_9H_8O_4$. The authors examine its calcium, barium, and sodium salts; its ethylic ether; its decomposition when heated with dilute hydrochloric acid; its behaviour with chloride of phosphorus, dichlorethylen-protocatechuic acid being the result; its preparation from carbo-hydrochinonic acid, which latter the authors consider completely identical with protocatechuic acid.

Some New Compounds of the Naphthalin Group. J. P. Battershall.—The author's object was to find in the naphthalin group representatives of the aldehyds and the true alcohols. He succeeds in obtaining and examining isonaphthoe aldehyd, $C_{10}H_7CHO$; hydroisonaphthamide, $(C_{10}H_7CH)_3N_2$; two isomeric acids α and β sulpho-naphthoeic acids and the barium, calcium, potassium, and copper salts of the former; oxynaphthoeic acid; sulphoisonaphthoeic acid with its barium salt; and oxyisonaphthoeic acid.

On a Change in Cast-Iron Produced by the Action of a Mineral Sulphur Water.—Dr. E. Priwoznik.—An iron water-pipe which had been exposed for twelve years to the action of water rich in the sulphide of hydrogen was examined. The innermost stratum consisted of—

Hydrated oxide of iron	81.08
Free sulphur	12.29
Sulphide of iron	4.48
Hygroscopic water	0.57
Nickel, cobalt, magnesia, silicic acid (soluble and insoluble), traces of carbon, and chlorides of ammonium and sodium ..	1.58

100.00

This stratum is, therefore, an intimate mixture of hydrated oxide of iron, sulphide of iron, and sulphur. The hydrated oxide has the composition $2Fe_2O_3 \cdot 3H_2O$, and is therefore identical with limonite. The middle stratum contained 79.2 per cent of metallic iron, and the exterior 92.6.

On Sulph-Hydantoin (Glycolyl-Sulphurea).—Richard Maly.—The author obtains monochloracetyl-sulphurea by the mutual reaction of monochloracetic acid and sulphocarbamid. From this product sulph-hydantoin is readily obtained.

Determination of the Boiling-Point of Liquids at a Normal Atmospheric Pressure of 760 m.m.—Dr. H. Bunte.—The author has devised an apparatus for dispensing with correction for the varying barometric pressure.

Preparation of Trimethyl-Carbinol by the Method of Linnemann.—A. Butters.—The author criticises Linnemann's process, and seeks for an explanation of the details necessary for success.

Berichte der Deutschen Chemischen Gesellschaft zu Berlin,
July 14, 1873.

On a New Deposit of Struvite.—Robert Otto.—In pulling down a house in the Knochenhauer Strasse, in

Brunswick, there was found about seven feet below the level of the pavement a stratum of decomposed excrement several feet thick, and interspersed with crystals which, according to their chemical and physical properties, consist of struvite.

Chemical Composition of Vesuvian.—C. Rammelsberg.—Former researches seemed to show that the composition of garnet and vesuvian were identical—a result confirmed upon the whole by the experiments of Magnus. The more recent analyses of the author, as well as those of Hermann and Scheerer, indicated the general formula, $R_{15}R_4Si_{15}O_{60}$. Magnus found that the vesuvian of Wilni lost 0.7 per cent on ignition; the author showed that in all other cases this loss amounted to 2 to 3 per cent, and consisted of water. The yellow and brown vesuvian of Mongoni, the vesuvians of Ala, Zermatt, Haslan, and Wilni were re-examined. In all, $R:Si=1:3.5$; in all except that of Wilni, $R:R=1:4$, and $(H,K):R=1:2.66$; in that of Wilni, $R:R=1:4.5$, and $(H,K):R=1:9$. Hence, for the majority, the formula is $H_3R_8R_2Si_7$, and for that of Wilni $HR_9R_2Si_7$.

On Certain Derivatives of Normal Propyl Alcohol.—H. Roemer.—The author has prepared and examined the mercaptan, C_3H_7SH ; a mercaptid, $(C_3H_7S)_2Hg$; the propyl-xanthogenate of potassa, a tripropyl-biuret,—
 $CON_2(C_3H_7)_3CONH_2$;

tetra-propyl-ammonium-iodide, and tetra-propyl-ammonium-oxyhydrate.

On Pyruvic Acid.—C. Böttinger.—The author had previously shown that during the transformation of pyruvic acid into uvitinic acid, the intermediate product hydrovinic acid is concerned. More recently he has prepared large quantities of pyruvic acid to examine in detail the transformation of basic hydrovinate of baryta, and especially to examine the residual syrupy acid named by Tinkle uvitonic acid.

On Chlortoluols.—H. Hübner and W. Majert.—The authors have formed and examined the ortho-chlortoluol sulphates of baryta, lime, lead, potash, soda, copper, copper-ammonia, and ammonia; the acid ortho-chlortoluol-sulphobenzoates of potash, baryta, and lead; the metatoluol sulphates of baryta and lead; the β -parachlortoluol sulphates of baryta, lime, lead, potash, copper, and copper-ammonia; and the α -para-chlortoluol sulphates of baryta and soda.

On Amido-Benzol, and a Simple Preparation of Meta-Diamidobenzol.—H. Hübner and H. Retschy.—If two constituents differing from hydrogen are introduced into benzol two pairs of compounds will be derivable, which may possibly be only distinguished by the manner of the combination of the atoms of carbon. With this purpose the authors examine diamidobenzol.

On Isomeric Brom-Toluidines.—H. Hübner and P. E. Róos.—The authors have found and examined a parabromnitro compound, and obtained by amidising it α -parabromtoluidin, and certain of its salts.

On Meta-bromtoluol.—H. Hübner and E. A. Grete.—The authors dissolved meta-bromtoluol in fuming sulphuric acid, and examined its barium salt.

On Benzyl-Dichloride Simultaneously Treated with Chlorine and Nitric Acid.—H. Hübner and F. Bente.—One of the authors had on a former occasion begun to examine the question whether all elements or groups of a decidedly homologous character, whether decidedly chemico-negative (acid) or chemico-positive (basic), replace the same atom of hydrogen in hydrocarbons. In the majority of cases the behaviour of such bodies was found to be absolutely identical. Certain exceptions, however, became apparent. Thus Beilstein and Kuhlberg observed that benzyl-dichloride with chlorine yields para-chlor-benzyl dichloride, $C_6H_4ClH_2.CCl_2$, and, on oxidation, para-chlor-benzoic acid, whilst benzyl dichloride with nitric acid yields a nitro-compound, which, on oxidation, gives meta-nitro-benzoic acid, instead of

para-nitro-benzoic acid as might be expected. This subject the authors have further examined.

Absorption of Ozone in Water.—L. Carius.—The author has previously shown that ozone can be absorbed by water unchanged in quantities not inconsiderable. He now finds that at the temperature 0° , and a pressure of 0.76 m.m., 1.346 c.c. of ozone were absorbed by 100 c.c. of water; this is independent of the amount of oxygen absorbed. The ozone used in these experiments was obtained by electric action.

Relative Position of the Lateral Links in Zincke's Hydrocarbons.—Br. Radziszewski.—A purely theoretical, or rather hypothetical, paper.

Remarks on the Structure of Aromatic Bodies.—Br. Radziszewski.—The same remark applies to this paper.

On Aromatic Phosphorus Compounds.—A. Michaelis.—The author has examined—Phosphenylchloride, phosphenyl tetrachloride, phosphenyl chlorobromide, phosphenyl chlorotetrabromide, phosphenyl oxychloride, and phosphenylic acid.

On Steam Press Filters.—Arnold Heintz.—The apparatus described is ingenious, and will probably be useful. The description would be unintelligible without the accompanying diagram.

MISCELLANEOUS.

The Adulteration Act.—The Board of Works for the district of Greenwich has just complied with the requirements of the Local Government Board in appointing a public analyst, under the provisions of the Adulteration Act. Out of seven candidates for the appointment, at the meeting of the Board on Wednesday, Mr. Wigner, of 79, Great Tower Street, public analyst for Plumstead district, was chosen.

To Fasten Leather upon Metal.—F. Sieburger recommends the process proposed by the late Prof. Fuchs:—One part of crushed nutgalls is digested six hours with eight parts distilled water, and strained. Glue is macerated in its own weight of water for twenty-four hours, and then dissolved. The warm infusion of galls is spread upon the leather, the glue solution upon the roughened surface of the warm metal, the moist leather is pressed upon it and then dried, when it adheres so that it cannot be removed without tearing.—*Polyt. Notizbl.*

PATENTS.

ABRIDGMENTS OF PROVISIONAL AND COMPLETE SPECIFICATIONS.

Improvements in treating certain gases for lighting and heating purposes, and in combining atmospheric air therewith. Charles Weightman Harrison, High Holborn, Middlesex. January 1, 1873.—No. 1. The novelty of this invention consists in carburetting or increasing the proportion of carbon in hydrocarbon gases, such as coal-gas, and afterwards mixing or combining therewith atmospheric air.

Improvements in apparatus employed in the manufacture of salt. Otto Ernest Pohl, salt manufacturer and merchant, Liverpool. January 1, 1873.—No. 4. This relates to evaporating apparatus in which the flames or heating gases are passed between two pans, and consists in covering the top of the bottom pan with sheet-iron or other material, preferably formed channelwise when viewed in transverse section. The bottom pan is made wider than the top one, to allow rakes to be conveniently used.

Improvements in treating waste products and other materials containing zinc for the purpose of recovering zinc and other metallic products therefrom, and in apparatus to be employed for that purpose. Charles Boundy, metal broker, Birmingham. January 1, 1873.—No. 17. According to this invention the waste product or material, consisting principally either of hard spelter, old zinc, new zinc cuttings, or zinc riddlings from galvanisers' ashes, is placed upon the top of an incline, forming the bed of a muffle or nearly closed chamber, and heated so as to sweat from out of it the zinc, which zinc runs down the said inclined bed, carrying with it any lead which may be contained in the material, and also solid particles of foreign matters. The liquid metal collects in the first of a set of receivers situated at the bottom of the bed. In the first receiver a large portion of the solid matter carried with the metals falls to the bottom. The metal in this receiver is removed from time to time, the upper part being poured back, and

the lower part being cast into ingots and treated again. As the first receiver becomes filled, the zinc overflows into the next receiver, and so on, where a spontaneous separation of the kind described takes place. The separated and purified zinc finally collects in a large pan or reservoir, and may be cast into ingots or otherwise. Before treating zinc riddings from galvanisers' ashes by the process described, they undergo a preliminary treatment for the purpose of utilising the sal-ammoniac and oxide of zinc contained in the said ashes.

Improvements in the manufacture of paints. William Britton Stephens, 67, Strand, Westminster. January 3, 1873.—No. 35. The application and use of slaked lime or plaster of Paris, one or the other, or both, instead of, or in combination with, the usual bases employed in the manufacture of paint.

Improvements in the purification of water, and in the means and apparatus employed for that purpose. Gustav Bischof, Professor of Technical Chemistry, Andersonian University, Glasgow. January 3, 1873.—No. 38. This invention has reference to the process of purifying water by filtering it through spongy iron, for which Letters Patent No. 2516 of 1870 were granted to the petitioner. The present invention consists in causing the water to filter through marble or limestone after passing through the spongy iron in order to remove the iron taken up by the water. Filters for this purpose are described, consisting of a vessel with perforated bottom containing the spongy iron, placed above a vessel with perforated bottom containing the marble or limestone, and arrangements are described whereby the water, after filtering through the spongy iron, is made to rise to the level of the spongy iron again before flowing down on to the marble or limestone, in order to keep the spongy iron always immersed. Animal charcoal may also be employed in place of the marble or limestone for retaining the iron.

An improved process and apparatus for extracting oleaginous or fatty matters from liquid or solid substances. William Gordon Thompson, manufacturing chemist, Manchester. January 3, 1873.—No. 42. The object of this invention is to separate oleaginous and fatty matters from various substances with which they may be combined, so that such oily or fatty matters when separated may be applied for various purposes in the arts.

Improvements in means or apparatus for the distillation of ammoniacal liquors, which improvements are also applicable in the distillation of other liquids, and in the concentration of soluble salts. Alexander Angus Croll, civil engineer, Coleman Street, London. January 4, 1873.—No. 45. The invention relates to means by which the liquid matter to be acted upon is received into the upper of a series of evaporating trays or chambers, and, in overflowing that, passes to the next, and thence to each in succession until it arrives at the lowest, which is that immediately over and surrounding the fire. The heat from the fire passes up through the centre of the lower chamber, thence radially over the liquor in that chamber and under the chamber next above, and thence under and over each to the outlet. The fire-door of the furnace is sealed after the supply of each charge, to cause all the atmospheric air to pass through the fire, and such air is forced upwards or forwards where the vapour has to pass through another media, as in the manufacture of sulphate of ammonia, or it may be drawn by vacuum.

Improvements in obtaining valuable substances derivable from residual liquors produced in the manufacture of alum from phosphates of alumina. Peter Spence, manufacturing chemist, Newton Heath, Manchester. January 4, 1873.—No. 50. This invention refers to obtaining valuable substances from the liquor arising from the manufacture of alum by the process patented by the present inventor dated June 9, 1870, No. 1676.

NOTES AND QUERIES.

Pure Anthracen.—Could any of readers kindly inform me of any accurate method of estimating the amount of pure anthracen in crude anthracen. I have tried one or two methods considered to be the most accurate, but these give far from good results. I shall feel greatly obliged to anyone who can favour me with an answer.—W. C. P.

Carbolic Soap.—I would be obliged if your readers could give me any information about the manufacture of carbolic soap used for sheep-washing. I believe it is made from soft soap and carbolic acid; I should like to know how the two ingredients are mixed together, in what quantity, the strength of the carbolic acid to be used, and how much to be used for washing each sheep, and if it is a cure for the scab in sheep.—B. WOTTON.

TO CORRESPONDENTS.

* Vol. XXVII. of the CHEMICAL NEWS, containing a copious index, is now ready, price 12s. 4d., by post, 12s., handsomely bound in cloth, gold lettered. The cases for binding may be obtained at our office, price 1s. 6d. Subscribers may have their copies bound for 2s. 6d. if sent to our office, or, if accompanied by a cloth case, for 1s. Subscribers wishing to complete their sets of volumes are requested to apply to the publisher, who will give them information respecting scarce numbers and volumes. Vol. xxviii. commenced on July 4th, and will be complete in twenty-six numbers. READING CASES, price 2s. 6d. each, post free, may also be obtained at the Office.

J. G. F.—Our "Students' Number," which will be published early next month, will contain full information respecting the examinations for B.Sc. and D.Sc. degrees.

J. H. F.—We do not know the composition of "Oroide of Gold" or "Persian Silver."

G. A.—Your communication does not contain sufficient novelty to warrant its insertion.

Chemical Technology, or Chemistry in its Applications to the Arts and Manufactures. By THOMAS RICHARDSON and HENRY WATTS. Second Edition, illustrated with numerous Wood Engravings.

Vol. I., Parts 1 and 2, price 36s., with more than 400 Illustrations.

Nature and Properties of Fuel: Secondary Products obtained from Fuel: Production of Light: Secondary Products of the Gas Manufacture.

Vol. I., Part 3, price 33s., with more than 300 Illustrations.

Sulphur and its Compounds: Acidimetry: Chlorine and its Bleaching Compounds: Soda, Potash: Alkalimetry: Grease.

Vol. I., Part 4, price 21s., 300 Illustrations.

Aluminium and Sodium: Stannates, Tungstates, Chromates, and Silicates of Potash and Soda: Phosphorus, Borax: Nitre: Gun-Powder: Gun Cotton.

Vol. I., Part 5, price 36s.

Prussiate of Potash: Oxalic, Tartaric, and Citric Acids, and Appendices containing the latest information and specifications relating to the materials described in Parts 3 and 4.

BAILLIERE and Co., 20, King William Street, Strand.

TECHNICAL EDUCATION.

SCIENCE AND ART DEPARTMENT.

Royal College of Science for Ireland,
STEPHEN'S GREEN, DUBLIN.

This College supplies, as far as practicable, a complete course of instruction in Science, applicable to the Industrial Arts, especially those which may be classed broadly under the heads of CHEMICAL MANUFACTURES, MINING, ENGINEERING, and AGRICULTURE.

A Diploma of Associate of the College is granted at the end of the Three Years' Course.

There are Four Royal Scholarships, of the value of £50 each yearly, with free education, including Laboratory instruction, tenable for two years. Two become vacant each year. They are given to Students who have been a year in the College.

The fees are £2 for each Course, or £10 for all the Courses of each year, with the exception of Laboratory, the fee for which is £2 per month, or £12 for the entire Session.

SUBJECTS OF INSTRUCTION.

Applied Mathematics and Mechanics, Mechanism and Machinery, Descriptive Geometry, Geometrical and Mechanical Drawing, Experimental Physics, Chemistry (Theoretical and Practical), Botany, Zoology, Geology, and Palaeontology, Mining, Surveying, Agriculture. The Session commences on MONDAY, OCTOBER 6th.

Programmes may be obtained on application to the SECRETARY, Royal College of Science, Stephen's Green, Dublin.

FREDERICK J. SIDNEY, LL.D., Secretary.

BERNERS COLLEGE of CHEMISTRY.—

EXPERIMENTAL MILITARY and NAVAL SCIENCES, under the direction of Professor E. V. GARDNER, F.R.S., &c., of the late Royal Polytechnic Institution and the Royal Naval College.

The Laboratory and Class Rooms are open from 11 to 5 a.m., and from 7 to 10 p.m. daily.

Special facilities for persons preparing for Government and other examinations.

Private Pupils will find every convenience.

Analyses, Assays, and Practical Investigations connected with Patents, &c., conducted.

For prospectus, &c., apply to Prof. E. V. G., 44, Berners-street, W

THE LIVERPOOL COLLEGE OF CHEMISTRY, 96, DUKE STREET, LIVERPOOL.

Specially Devoted to the Study of CHEMISTRY, TECHNOLOGY and ASSAYING.

Laboratories open throughout the Year.

MARTIN MURPHY, F.C.S., &c., Principal (Successor to the late Dr. SHERIDAN MURPHY).

A Special Laboratory is devoted to Commercial Analyses of every description, and to Mineral Assays.

Manufacturers' and Smelters' Analyses and Assays undertaken on Contract.

Patentees and Inventors Advised and Assisted. Works and Mines Inspected. The Erection of Manufacturers' Plant Supervised, &c.

Terms and Fees VERY MODERATE.

Further Particulars and Full Prospectus on application to The Principal, MARTIN MURPHY, F.C.S. &c.

THE CHEQUE BANK, LIMITED,

HAS COMMENCED BUSINESS AT ITS OFFICES,
FALL MALL EAST,
AND
124, CANNON STREET, E.C.

The GUARANTEE FUND of £100,000 CONSOLS has been invested in the names of the following

TRUSTEES.

ROBERT DALGLISH, Esq., M.P.
CUTHBERT E. ELLISON, Esq., J.P.
SAMUEL MORLEY, Esq., M.P.
W. H. SMITH, Esq., M.P.

The cheques of the Cheque Bank supply a new, safe, and universally applicable method of paying and transmitting small amounts of £10 and under.

Each cheque will bear stamped on its face the maximum amount for which it can be filled up, but the maximum amount must be previously deposited, and thus no account can be overdrawn. All cheques are crossed, and payable only to order.

The cheques are supplied in books of ten each, costing 1s., being 10d. Government duty, and 2d. Bank commission.

Applications for Cheques to be made at the Offices as above, or at any of the following Bankers, where the funds of the Cheque Bank will be deposited:—

THE BANK OF ENGLAND.
THE WESTERN BRANCH OF THE BANK OF ENGLAND, Burlington Gardens, Bond Street.
GLYN, MILLS, & CO.
WILLIAMS, DEACON, & CO.
NATIONAL PROVINCIAL BANK OF ENGLAND.
DIMSDALE, FOWLER, BARNARD, & CO.
CONSOLIDATED BANK, LIMITED.
ALEXANDERS, CUNLIFFES, & CO.
NATIONAL BANK OF SCOTLAND.
ALLIANCE BANK, LIMITED.
JAY COOKE, McCULLOCH, & CO.
HERRIES, FARQUHAR, & CO.
R. TWINING & CO.
CITY BANK.
UNION BANK OF SCOTLAND.
MANCHESTER AND SALFORD BANK.
MANCHESTER AND COUNTY BANK.

FALL MALL EAST, S.W.,
11th August, 1873.

By order, S. J. NICOLLE,
Secretary and Accountant.

ESTABLISHED 1798.

ROBERT DAGLISH & CO., BOILER MAKERS, ENGINEERS, AND MILL-WRIGHTS, BRASS AND IRONFOUNDERS, ST. HELEN'S FOUNDRY, LANCASHIRE.

Makers of every description of Chemical, Colliery, Copper Ore, Gold Mining, and Glass Machinery, including Crown, German Sheet, and Plate Glass Plant, as supplied to some of the largest Firms in England, Ireland, Scotland, and Wales.

Makers of the latest Improved Revolving Black Ash Furnace, with Siemens's Patent Gas Arrangement, and as used in the Manufacture of Soda.

Improved Valveless Air Engines, and Pumps for Acid Forcing, Air Agitators, Compressors for Collieries, and Weldon's Patent Chlorine Process.

Caustic, Chlorate, Decomposing, and Oxalic Pans.
Gas Producers for Heating Furnaces.

Pyrites Burners for Irish, Norwegian, and Spanish Ores.
Retorts, Acid, Gas, Nitric Acid, and Vitriol Refining.

Improved Steam Superheaters for Resin Refining, &c.
Improved Steam Sulphur Pans.

Photographs, and other information, supplied on receipt of Orders.

OXIDE OF IRON.

We are prepared to supply, on moderate terms,
HYDRATED PEROXIDE OF IRON (BOG OCHRE),
Same quality as supplied by us to several of the most extensive Glass Companies, and which has given entire satisfaction.

FRANCIS RITCHIE AND SONS, BELFAST.

PRACTICAL CHEMISTRY.

Laboratory, 60, Gower Street, Bedford Square, W.C.

Mr. Henry Matthews, F.C.S., is prepared to give instruction in all branches of PRACTICAL CHEMISTRY, particularly in its application to MEDICINE, AGRICULTURE, and COMMERCE.

The Laboratory is open daily, except Saturday, from ten to five o'clock; on Saturday, from ten till one o'clock.

Mr. Matthews is also prepared to undertake ANALYSES of every description.

For Particulars and Prospectuses, apply to Mr. Henry Matthews the Laboratory, 60, Gower Street, Bedford Square, W.C.

FOOT, BARRET, AND TEMPLE, BATTERSEA.

ACETIC & NITRIC ACIDS. MANUFACTURERS OF HYDRATE OF CHLORAL.

Chloride of Calcium (Purified Muriate of Lime),
total insoluble impurities under $\frac{1}{4}$ per cent.

CHLORIDE OF BARIUM (Muriate of Baryta), free from Iron and Lead, total impurities, water excepted, under $\frac{1}{4}$ per cent

GASKELL, DEACON, & CO.,

ALKALI MANUFACTURERS WIDNES, LANCASHIRE.

Silicates of Soda and Potash in the state of Soluble glass, or in CONCENTRATED SOLUTION of first quality, suited for the manufacture of Soap and other purposes, supplied on best terms by W. GOSSAGE and Sons, Widnes Soapery, Warrington.

London Agents, CLARKE and COSTE, 19 and 20, Water Lane, Tower Street, E.C., who hold stock ready for delivery.

LIEBIG COMPANY'S EXTRACT OF MEAT.

—None genuine without the Inventor's facsimile in blue being on the Trade-mark label and outer cover. Pure condensed Essence of Beef Tea, excellent economic flavouring stock for soups, sauces, and made dishes.

"Food for the nerves." (Liebig).

T. HOLT & CO., MAKERS OF PURE OIL & BLACK SOAPS, CHEMICALS, &c.,

FOR MANUFACTURERS AND DYERS.

SALAMANCA OIL SOAP, DYE, AND CHEMICAL WORKS,
VAUXHALL WALK, LONDON.

MEDICAL ELECTRICITY. HOW TO USE SUCCESSFULLY,

With safety and success, in all cases of weakness, low spirits, despondency, languor, exhaustion, constipation, nervousness, muscular debility, loss of strength, appetite, &c., &c.

WITHOUT MEDICINE,
or recourse to spurious appliances or pamphlets issued by men devoid of medical education.

Full printed instructions and diagrams for Invalids,

Post free, two stamps, from

Dr. HAYWARD, M.R.C.S., L.S.A., 14, York Street, Portman Square, London, W.

Electricity revives the failing functions of life, and thus imparts energy and fresh vitality to the exhausted and debilitated constitution, and may fairly be termed the *Foundation of Health*.

Methylated Spirits.—David Smith Kidd,
Licensed Maker, Commercial Street, Shoreditch, N.E.
Also FINISH, FUSEL OIL, and RECT. NAPHTHA.

LECTURE ON THE SUN. Illustrated by DIAGRAMS, MODELS, and CHEMICAL EXPERIMENTS. NOTICE.—Mr. DART is appointed to Lecture at the Royal Polytechnic, Falmouth, on the 29th inst., and expects to remain in Cornwall the first week in September, and be on the return route between the 7th and 14th. For vacant nights and further particulars please address, R. DART, 12, Bedford Street, Strand, London.

N.B.—Mr. D. wishes an Engagement between London and Bath for Monday, the 25th inst. Terms, Two Guineas.

THE CHEMICAL NEWS.

Vol. XXVIII. No. 717.

THE CHEMICAL CONSTITUTION OF SUCCINIC, MALIC, AND TARTARIC ACIDS, CRITICALLY EXAMINED AND INTERPRETED FROM THE STAND-POINT OF THE "TYPOSNUCLEUS" THEORY.

By OTTO RICHTER, Ph.D.

(Continued from p. 77).

PART II.

On the Principal Molecular Changes which the Water-Salts of Succinic, Malic, and Tartaric Acids are prone to experience under the influence of Heat and Oxidising Agents.

This part may be conveniently divided into two chapters, the one to treat on the effects of heat, and the other on the effects of oxidising agents, upon these compounds.

CHAPTER I.

On the Effects of Heat upon the Water-Salts of Succinic, Malic, and Tartaric Acids.

(1). Let us, in the first place, contemplate the effects of temperature when the ordinary succinate is mixed with hydrate of lime. On treating the resulting lime-salts with hydrochloric acid, carbonic acid is given off, and a substance is found in the distillate which, in composition and properties, agrees with the normal propionate of water. In musing upon the nature of this evidently very complicated reaction, I soon came to comprehend that its course must be marked by a number of well-defined transition products—among others, by the occurrence of two isomeric modifications of the succinate. One of these isomerides, to which I will apply the term "iso-succinate," is no doubt identical with a compound realised some time ago by boiling one of the two varieties of cyan-propionate with potash ley (*vide* Part III.); while the other, to which I will apply the term "para-succinate," remains yet to be discovered. The rationale of the entire process may be given in the following words:—

In the first stage, the succinate of lime splits up into 2 molecules of water, derived from the formylic alcohol ally and the unknown succinate of lime—

whose formula implies that the liberated formen has coalesced with the formen adjunct of the unaltered principal under the double form of biformen or deacetylen. At the same time the two liberated water molecules become decomposed, so as to yield up their oxygen to the oxalous acid ally, while their hydrogen unites with the biformen or deacetylen adjunct. The resulting product is, therefore, a molecule of iso-succinate of lime—

In the second stage, the colligated methylen-formylic or acetylic alcohol breaks up into 2 molecules of water and the corresponding hydrocarbon, which instantly reunites as adjunct with the oxalous acid principal; at the same time the two liberated water molecules suffer decomposition, so as to yield up their oxygen to that principal, while their hydrogen unites with its freshly-acquired

hydrocarbon adjunct. The resulting product is, therefore, the para-succinate of lime—

with methan-formen or ethylen for an adjunct.

Before proceeding farther, it behoves me to state that this latter isomeride differs materially from its two predecessors, in this respect: that it is no longer amenable to the original type of de-alcohol-conjugated polyatomic water-salts, but that it has suddenly become transferred to the typically-distinct class of hydrocarbon-conjugated polyatomic water-salts (a species of typical metamorphosis which, in my system of notation, is indicated by the substitution of the symbol (!) for the symbol (~)).

Finally, a mere glance at my formula suffices to show, that the carbonic acid must derive from the oxalic acid ally of the para-succinate, which has become oxidised at the expense of its freshly-acquired water base, while the liberated hydrogen unites with the hydrocarbon adjunct of the oxalic acid principal. The end product of this highly-interesting and instructive reaction is, therefore, the propionate of lime—

the α variety of which I believe to be identical with the iso-propionate of our handbooks, while the β variety corresponds to the normal propionate.

(2). Let us, in the second place, consider the effects of heat upon the ordinary malate. These effects may be more advantageously studied and explained in connection with the process of fermentation, which the malate is known to undergo whenever the combined energies of lime-water, a so-called ferment, and a suitable temperature are made to bear upon it. The chief products of the reaction consist in a mixture of the lime-salts of carbonic, iso-lactic (ordinary lactic), acetic, succinic, and butyric acids: and the principal molecular changes which characterise the different stages of this hitherto obscure and unfathomable process may be described as follows:—

In the first stage, the malate of lime splits up into 2 molecules of water and the well known malate of lime—

the heterologue of the afore-mentioned succinate of lime, and the β variety of which I hold to be identical with the fumarate of our handbooks. At the same time the two liberated water molecules suffer decomposition, so as to yield up their oxygen to the oxalous acid principal, while their hydrogen unites with the biformen or deacetylen adjunct. The resulting product is, therefore, the isomalate of lime—

The second stage is marked by the resolution of this lime-salt into carbonic acid, derived from the oxidation of the oxalic acid ally at the expense of its own freshly-acquired water-base, and the isolactate of lime—

the α variety of which remains yet to be discovered, while the β variety corresponds to the ordinary lactate of our handbooks.

It is upon the new basis of the isolactate of lime that I shall now proceed to expound the molecular changes, which accompany the production of the acetate and succinate of lime on the one hand, and the butyrate of lime on the other hand.

In the first place, as regards the acetate and succinate of lime. These two lime-salts, which require for their production the co-operation of 1 molecule of isolactate and 2 molecules of unaltered malate of lime, are formed simultaneously, in virtue of the following reaction:—First of all, the isolactate of lime resolves itself into a molecule of methylen-formylic or acetylic alcohol, both of which speedily merge into the isomeric acetate of water and into a molecule of formate of lime. The acetate then becomes oxidised into the acetate at the expense of 2 molecules of water, while the liberated hydrogen serves to reduce one of the accessory molecules of malate, with production of a molecule of succinate of lime. In like manner, the formate becomes oxidised into the formate of lime at the expense of 2 molecules of water, while the liberated hydrogen serves to reduce the other accessory molecule of malate, with production of a second molecule of succinate of lime. Finally, the newly-formed acetate of water, by transposing with the formate of lime, gives rise to acetate of lime and the unstable formate of water, which speedily resolves itself into 2 molecules of water and carbonic acid.

In the second place, as regards the butyrate of lime. This compound, which requires for its generation an excess of ferment, as well as a higher temperature, is derived from two molecules of isolactate, through the following series of molecular changes:—In the first stage, one of the isolactate of water molecules breaks up into a molecule of methylen-formylic or acetylic alcohol and a molecule of formate of lime. The formic acid constituent of this latter instantly unites as ally with the formic acid principal of the other molecule of unaltered isolactate. The resulting bibasic meta lime-salt is therefore expressed by the formula—

With the aid of 2 molecules of water, the liberated alcohol has at the same time become converted into the glycolic alcohol—

We now arrive at a remarkably interesting feature of the process, which is, that the ensuing molecular changes are due entirely to the reducing action of the glycolic alcohol on the afore-mentioned meta lime-salt. Accordingly, the first stage is marked by the separation of 2 molecules of hydrogen from the methylen adjunct of the glycolic alcohol, and their immediate conversion into 2 molecules of water at the expense of the formic acid principal of the meta lime-salt. The resulting products are, therefore, a molecule of the reduced, but still bibasic, meta lime-salt—

and a molecule of de-glycolic alcohol, which speedily merges into the isomeric glycolite of water—

Subsequently, the reduced meta lime-salt, after transposing with the glycolite of water, becomes converted into the monobasic lime-salt—

which, by the loss of 2 molecules of water, derived from the splitting up of the formylic alcohol ally, becomes still further changed into the lime-salt—

The next stage is marked by the conversion of the newly-formed glycolite of lime into the glycolate—

at the expense of 2 molecules of water, while the liberated hydrogen unites with the hydrocarbon adjunct of the afore-mentioned lime-salt, with production of the isobutolactate of lime—

In the last stage, the ethylen-formylic or allylic alcohol of this latter compound splits up into 2 molecules of water and the corresponding hydrocarbon, which, by its immediate union with the formic acid principal, gives rise to a molecule of crotonate of lime—

at the same time, the two liberated water molecules suffer decomposition, so as to surrender their oxygen to the glycolate, while their hydrogen unites with the hydrocarbon adjunct of the crotonate. The resulting products are, therefore, a molecule of butyrate and a molecule of glycolate of lime, with the respective formulae—

and—

The preceding train of reasoning, regarding the soundness of which I must leave the reader to judge for himself, clearly proves that the evolution of hydrogen gas, which never fails to accompany the butyric fermentation, is due entirely to a secondary reaction, the cause of which is not far to seek. For we may well suppose that, under the combined influence of excess of ferment and a high temperature, the aforesaid glycolate of lime splits up into the formylic alcohol and the formate of lime, which, by transposing with the formite of water, into which the formylic alcohol has been made to pass, gives rise to formite of lime and the unstable formate of water. The latter splits up into 2 molecules of water and carbonic acid, while the formite becomes oxidised, first into the formate, and afterwards into the formate of lime, indubitably at the expense of the aqueous solvent, from which an equivalent quantity of hydrogen gas must therefore become evolved.

(3). Let us, in the last place, contemplate the effects of temperature upon the ordinary tartrate of water. When this substance is heated up to a certain point, it loses 2 molecules of water, and along with it the character of solubility; at the same time it ceases to exhibit the acid properties of an organic water-salt, while a few degrees below that point it retains still a distinctly acid reaction. Now, at first sight, and with no other facts to guide us, we might naturally take the insoluble product to be the ortho-tartaric anhydride—

but, after examining more closely into these relations, we are constrained to admit that this body is only an isomeric modification of the former, and so far as I know, still unisolated compound. I have come to the conclusion that the insoluble product is the meta-tartaric anhydride—

and I consider that the conversion of the soluble variety, or the so-called tartrate—

into this body is readily explained on the hypothesis that the two oxalic acid constituents become oxidised at the expense of their own water bases, while the liberated hydrogen re-unites as adjunct with the carbon nuclei of the freshly-formed bicarbonic acid constituents. It is self-evident, that the re-conversion of the meta-tartaric anhydride into the tartrate must be attended by a series of molecular changes, in which the order of molecular movements is absolutely reversed.

The reader cannot help admitting, that the two kinds of molecular rearrangement just described, in virtue of which an organic water-salt becomes suddenly deprived of one of its most characteristic chemical properties, and as suddenly re-endowed again, is a fact of the deepest theoretical value and significance. Having, in the course of my researches, become acquainted with a considerable number and variety of analogous cases, I have found it expedient to make use of the terms "ortho-genesis" and "meta-genesis," the former to denote the conversion of a meta-anhydride into the corresponding ortho water-salt, and the latter to denote the conversion of an ortho water-salt into the corresponding meta-anhydride.

The preceding remarks will, I trust, enable the reader to comprehend the precise nature of the molecular changes which accompany the action of heat on the ortho-tartrate up to the point where it changes into the meta-tartrate—

And here I may notice a peculiarity of the tartrate, whereby it differs remarkably from its two lower heterologues, and which consists in the circumstance, that its dehydration is invariably preceded by the formation of the meta-tartrate, while compounds corresponding to a meta-succinate and meta-malate, although theoretically possible, are as yet entirely unknown. This difference may be accounted for on the hypothesis that, in the existing conditions of the experiment, the tartrate is prone to merge into the isomeric meta-anhydride—

corresponding to the bibasic meta water-salt which, the reader will recollect, was encountered as a transition product in the oxidation of the tetratomic butylen erythrol.

Let us, further, suppose that this compound resolves itself into 2 molecules of water and the meta-tartaric anhydride—

and that these two water molecules, instead of being eliminated, are instantly brought to re-unite as water bases with the acid constituents of the anhydride; we shall then, by this practical application of the above-mentioned method of meta-genesis, have put ourselves in possession of a powerful argument in support of the assertion, that the meta-tartrate of water is really constructed on the pattern of the formula assigned to it.

In all the cases hitherto examined, the bodies obtainable by the action of heat on the tartrate have this point in common, that they contain the same equivalent number of carbon molecules as the alcohol, from which they are descended. Let us now contemplate the case when, through the more energetic interposition of the same physical agent, the tartrate is forced to part with a certain portion of that element. In this process the carbon is always eliminated under the form of carbonic acid, while

the contents of the receiver are found to consist of the ordinary glycerate of water—

Evidently the carbonic acid is here, as it is in the majority of cases, derived from the oxalic acid ally, which becomes oxidised into this anhydride at the expense of its own water base; while the liberated hydrogen, by re-uniting as adjunct with the oxalic acid principal, transforms it into a formic acid principal. The resulting product is, therefore, a molecule of the glycerate, as formulated above. When the glycerate is strongly heated in its turn, it splits up into 2 molecules of water, derived from the formen-holding ally, and the pyruvate—

which, by this formula, is shown to occur in two isomeric modifications. Finally, when the pyruvate is strongly heated in its turn, 2 molecules of this compound are observed to conspire towards the production of 1 molecule of the ordinary pyrotartrate, while carbonic acid is given off.

In this highly interesting and instructive metamorphosis, one of the two pyruvate of water molecules resolves itself, on the one hand, into a molecule of formate of water, the formic acid constituent of which instantly unites as ally with the formic acid principal of the other unaltered pyruvate of water molecule, with production of the bibasic meta water-salt—

and, on the other hand, into the biformylic or deacetylic alcohol, which (after previous conversion of the β into the α variety) speedily surrenders first the one and then the other of its constituent formen molecules to the biformen or deacetylen adjunct of the aforesaid meta water-salt, with production of a still more highly carbonated bibasic meta water-salt—

Subsequently, the formic acid ally of this compound becomes oxidised into a formic acid ally at the expense of the two liberated water molecules, while their hydrogen unites with the complex carbon adjunct. By the method of ortho-genesis, the resulting bibasic meta water-salt—

becomes then converted into the isomeric ortho water-salt—

which speedily resolves itself into carbonic acid and the monobasic water-salt—

This latter, again, soon merges into the isomeric modification of the bibasic meta-pyrotartrate—

which, by the method of orthogenesis, is finally transformed into the ordinary or ortho-pyrotartrate—

As it is my intention of resuming the subject of pyro-tartaric acid in a future communication, the reader is now requested to scrutinise the contents of the second chapter.

CHAPTER II.

On the Effects of Oxidising Agents upon the Ordinary Malate and Tartrate of Water.

The chief products of this process are found to be the malonate and tartronate of water, while carbonic acid is given off in both cases. The formulæ—

and—

bear witness that, like their parent molecules, these two derivatives stand to each other in the relation of true heterologues, whilst the lowest member of this family-group, with the formula—

remains yet to be discovered.

The reader will at once admit that this triad of acid heterologues must be descended from the olefine-begotten triatomic propylene-glycerol, that being the identical alcohol which, by oxidation, is known to furnish the ordinary glycerate. The following two cases appear to me well adapted to elucidate the precise nature of those family ties, that connect the glycerate with the two compounds under consideration; but, before entering more deeply into this subject, I have deemed it advisable to interweave a few remarks explanatory of the genetic relations which subsist between the tartronate and divers other organic combinations, as, for example, the mesoxalate, glycolate, and glyoxalate. Thus, it is proved by experiment—
(1) That, under the influence of heat, the tartronate splits up into carbonic acid and the glycolate, according to the equation—

(2) that nascent hydrogen converts the mesoxalate into the tartronate, according to the equation—

where, in striking contrast with received notions, the reducing energies of the hydrogen are expended upon the carbonic oxide adjunct in preference to the more highly-oxidised oxalic acid principal; (3) that heat causes the mesoxalate to split up into carbonic acid and the glyoxalate, according to the equation—

Reverting again to the two cases proposed for analysis, I shall, in the first place, seek to interpret the molecular changes, which culminate in the production of the tartronate. A solution of the nitro-tartrate of water suffers decomposition even in the cold, the chief products being the tartronate, while carbonic acid and nitric oxide are evolved. The reaction is expressed by the equation—

$\frac{\text{H}_2\text{O}_2. \text{H}_2\text{O}_2. \text{H}_2\text{O}_2.}{2\text{C}_2; \text{H}_2\text{O}_2: 2\text{C}_2\text{O}_3 \sim 2\text{C}_2\text{O}_3 + 2\text{C}_2\text{O}_4 + 2(2\text{N}_2\text{O}_3)},$
= tartronate, and the accompanying molecular changes are thought to be as follows:—With the aid of 2 molecules of water, the

nitro-tartrate resolves itself, in the first stage, into 2 molecules of nitrate and 1 molecule of tartrate. The latter soon splits up into carbonic acid and the monobasic glycerate—

which speedily merges into the isomeric modification of the bibasic meta-glycerate—

By the oxidising action, first of one, and then of the other molecule of nitrate, the meta-glycerate is in the second stage made to pass into the meta water-salt—

and thence into the meta water-salt—

The third stage is marked by the resolution of this latter into 2 molecules of water and the meta-anhydride—

which, by the method of orthogenesis, becomes finally converted into the isomeric tartronate, as formulated above.

I shall, in the second place, seek to interpret the molecular changes which culminate in the production of the malonate. When ordinary malate of water is treated with bichromate of potash and sulphate of water in the cold, the chief product is found to be the malonate, while carbonic acid is evolved. In this process, the malate is first of all oxidised into the tartrate, which soon splits up into carbonic acid and the glycerate. From this point the molecular changes are precisely as in the former case, except that, owing to the more scanty and sluggish supply of oxygen, the process terminates with the formation of the above-mentioned meta water-salt—

which becomes finally reduced to the state of malonate by the same kind of metamorphosis I have just shown to accompany the production of the tartronate.

Great theoretical importance attaches to the fact that, at a certain temperature, the malonate splits up into carbonic acid and the ordinary acetate; and the reader, by taking his cue from my analysis of kindred phenomena, will not be slow to perceive that the intermediate product must be the para-malonate—

The kind of metamorphosis here referred to, so far from being of an exceptional character, is, by the annexed scheme, shown to be a feature common to a whole series of homologues. The first member of the para-series, viz., the para-oxalate, is still unknown, but I consider it highly probable, that the so-called oxalovinate—

is one of its ethylic ether derivatives. Under the influence of heat, this series of bibasic homologues is observed to give birth to a second series of monobasic homologues, which coincides in every respect with the series of the so-called fatty acids.

Having now presented the reader with a plain, intelligible, and, I trust, also correct analysis of the molecular changes, that accompany the natural production of the water-salts of succinic, malic, and tartaric acids in the living organism, I shall in the sequel endeavour to accomplish the analysis of the molecular changes, that accompany the artificial production of these compounds in our laboratories. The reader is, therefore, invited to ponder

TABLE OF GENETICALLY-RELATED WATER-SALTS OF THE FATTY ACIDS.

First Series of Acid Homologues.

Bibasic Water-Salts of the Fatty Acids.

Para-oxalate ..	$\frac{H_2O_2. H_2O_2.}{2C_2O_3 : 2C_2O_3} = 2C_2O_4 +$

Butyrate	$\frac{H_2O_2.}{a) 2(H_6C_4 : HC_2) : 2C_2O_3.}$ $\beta) 2H_7C_6 ;$

the third part of my programme, where a fresh crop of valuable experimental evidence will be laid before him in support of the new views and doctrines I have ventured to promulgate.

(To be continued.)

ON THE ASH OF DISEASED POTATOES.

By ALEXANDER S. WILSON.

THE CHEMICAL NEWS, vol. xxvii., p. 147, contains an interesting paper, by Mr. J. B. Hannay, on the "Inorganic Constituents of Sound and Diseased Potatoes." From the analyses there given, Mr. Hannay concludes that the amounts of potassium, chlorine, and sulphuric acid are greater in diseased tubers than in sound ones, whilst the amount of soluble phosphoric acid is less.

The analyses admit of some other generalisations, but the author has either overlooked them, or they have been omitted in your report. On looking over a table of analyses of the ashes of potatoes, as given in some works on agriculture, one is struck with the great discrepancies between the different analyses; and when we attempt to compare the analyses of diseased samples with these, the task is one of difficulty, for we are at a loss with which to compare them; hence, doubtless, arose those differences of opinion as to the increase or decrease of potash in diseased roots, which Mr. Hannay notices, and which he has avoided by making analyses of good and bad samples taken from the same field.

Some time ago I made an analysis of the ash of a sample of diseased potatoes, which I dug, in the end of last season, from a plot of ground which was, I should say, favourably situated for the development of the disease, and consequently unfavourably for that of the potato. The soil in which these potatoes were grown consisted, for the most part, of disintegrated sandstone and decayed vegetable matters; the season, it will be remembered, was an excessively wet one. Unfortunately I was unable to obtain a sample of sound tubers from the same lot, and the leaves and stems were so far decayed that I did not consider them suitable for analysis. The potatoes were the kind known as "regents," and the tubers themselves were very much diseased, so much so that I question if they could have been used for feeding cattle.

One source of discrepancy in analyses of this kind must be noticed. This is the earth, which adheres tenaciously to the tubers, particularly in the eyes, even of sound potatoes, and penetrates into the substance of the diseased tubers in such a way that its separation can only be effected by cutting away the part. In this way a large portion of the cuticle is removed; now, the cuticle differs considerably in composition from the rest of the root, and from this cause considerable errors may creep into results, even although all the earth may have been removed from the sample. In preparing this sample I carefully removed the earth from the exterior, and cut out those parts where the sand was so much mixed up with the diseased substance as to render this impossible. A large quantity of

the sample thus treated gave 1.07 per cent of mineral matter, which had the following composition:—

Potassium	44.51
Sodium	0.25
Magnesium	2.36
Calcium	1.12
Phosphoric anhydride	14.48
Sulphuric anhydride	5.57
Carbonic anhydride	15.80
Chlorine	1.37
Ferric oxide	0.53
Silica	2.89
Oxygen, equivalent to .K, Na, Mg, and Ca, minus equivalent proportion of Cl	11.22

100.10

On comparing these results with Mr. Hannay's, and with a number of analyses of sound tubers, I find that, so far as increase of potash and sulphuric acid are concerned, they confirm his conclusions; and, if they do not show that the phosphoric acid does not decrease, they at least show that some diseased tubers contain as much as some sound ones do; the chlorine, too, in this sample is less than in Mr. Hannay's sound sample. But what I wish particularly to direct attention to, is the small amount of lime and magnesia which the sample contains; in none of the analyses which I have consulted are the percentages so low as in this sample. Different observers state the percentage of magnesia in the ash of sound tubers at from 5 to 10 per cent; in this case it is only 3.94 per cent. In the two samples of diseased ash, Mr. Hannay only found 1.00 and 0.1 per cent of magnesia. Similarly, Mr. Hannay's, as well as my own, results show that the amount of lime is abnormally low in the diseased samples. In this case I found 1.77 per cent of lime; in the sound sample Mr. Hannay found 5.19 per cent, and considerably less in both the diseased samples. With regard to the sound sample, however, it may be observed that even, although these tubers were sound—that is, although they had not been attacked by the fungus,—still the vitality of these plants must have been considerably reduced by the unpropitious weather of last year, so as to render them liable to succumb on the deposition of the spores of the fungus on their stomata. This want of vitality may fairly be conceived as due to the presence of noxious, or the absence of necessary, substances in the juices of the plant, and such conditions must undoubtedly be the counterpart of the unfavourable circumstances under which the potato has laboured in many parts of the country, and in some years to a greater extent than in others. The potato plant is in every part of its structure strikingly adapted for a dry climate and light soil. When we consider that it has for many years been cultivated under the very reverse of these conditions, and that its structure has not varied to accommodate it to the changed circumstances, we cannot wonder that it has fallen the prey of its enemies.

With these considerations before us, I think that we

are justified in appealing to chemical science—to solve the problem as to the prevention of the disease—to suggest not a substance that will destroy the enemy, for this is next to impossible, but to give the plant such nourishment that will enable it to resist the adverse circumstances in which it is placed, as well as the attacks of its own peculiar enemies.

Some years ago, Professor Thorpe found, from the analyses of diseased and healthy orange trees, that, in the former, the amounts of lime and magnesia are deficient; the same thing, we have seen, is the case in the diseased potato plant.

It has lately been shown, by Dr. F. Crace Calvert, that lime is one of the few substances which we know that are capable of altogether preventing the development of fungi in organic solutions. He does not give any experiments relating to the action of caustic magnesia on fungi, but doubtless its action will be found to be similar.

Here, then, is a curious and, at the same time, significant fact—Diseased potatoes are deficient in lime salts: lime prevents the development of fungi. May not the development of fungi in the vessels of plants be furthered by this deficiency? The circumstances are such as scarcely to leave room for doubt. So far, then, theory and practice agree; lime has been found by experience to be useful in preventing the disease, and I cannot doubt that magnesia, if tried, will be found to have a similar effect.

ON THE ENERGIES OF THE IMPONDERABLES, WITH ESPECIAL REFERENCE TO THE MEASUREMENT AND UTILISATION OF THEM.*

By the Rev. ARTHUR RIGG, M.A.

(Continued from page 80.)

LECTURE III.

On the Energy of Vitality, with especial reference to the Measurement and Utilisation of it.

THE "Energy of Vitality" is a manifestation by motion of the unknown and unseen power which is associated with life—indeed that which may (perhaps) be said to constitute life itself. This vital power (some may call it force) is presented to our notice in two forms, the animal and the vegetable; hence the two sciences of zoology and botany.

In the distinctions laid down in the classification diagram, it will be observed that the energies are divided into potential and kinetic.

In seeds, in eggs, in frozen toads, in suspended animation, in hibernating animals, are examples of the potential energy of vitality. The power is there, but it awaits those surroundings which may convert this potential or dormant energy into kinetic or active energy. So long as a living body lives, it possesses kinetic energy; it has power to move. Such a power is not possessed by any dead body, although from external sources it may be introduced into one.

The energy of vitality is converted into the energy of affinity in the assimilation of food, into that of electricity in muscles and muscular action, into that of light as in glow-worms and certain fishes, and into that of heat as in warmth of the body. One peculiarity of this vital power is the ability to seize on that which is material, and to adapt or select therefrom whatever may be suited for its special purpose. The earliest or most elementary of the animal forms in which this vital power of adaptation displays itself is called a protoplasmic germ. This germ, or, as it may be described, this microscopical cell, if placed in congenial surroundings, manifests an energy of growth or reproduction which adapts these surroundings in a way and under an influencing power quite unknown to us. The power of gravity enclasp all matter, the power of vitality exercises a selectiveness from matter: gravity

influences all matter, but changes the shape of none; vitality changes the form of all its influences. For example: the process of fermentation is one in which a minute molecule possessed of a vital power can communicate a similar power to another molecule, this again to another, in each case appropriating or attaching the molecule to itself for awhile, and so producing a rapidity of what we call growth, which seems almost as a process of crystallisation when the water of solution is being evaporated.

Between the development of a crystal, however, and of life, there is this marked difference. A crystal grows by appropriating *like* molecules, and deals with them according to laws unknown to us; a body having vitality not only appropriates various molecules, but re-combines, re-forms, and rejects. These the crystal cannot do. The growth of a crystal is a phenomenon in physics, the growth of an animal is a phenomenon in chemistry. In both cases, the powers of reproduction or enlargement are mysterious. Although under the influence of vitality many forms of matter are produced, yet the crystalline one never appears; as soon, however, as the excretory processes is completed, or the vital power is withdrawn, then commences work of a crystalline character.

How vitality is transfused, or what it is, or in what contained, how nourished, or how destroyed, we know not. With the energy of vitality, as manifested in the processes of reproduction and growth, we are not this evening required to deal. Within that frame thus mysteriously developed, there are combinations of mechanical and chemical apparatus fulfilling conditions with which we are deeply concerned. This apparatus, however, does not from year to year retain the same power. Owing to the vital action, the apparatus with which we are to deal, whilst in incessant fluctuating change, yet attains a climax, then slowly subsides, then follows that phenomenon, even more mysterious, if possible, than any other of the vital ones, viz., their sudden cessation, which we call death. Neither in its earliest development nor in its mysterious cessation are those phenomena presented which are consequent upon energies we can either measure or utilise. Whence that comes which imparts vital energy, and whither it goes, are problems rather for human faith than human understanding. When an engineer has to estimate the power of a steam-engine, he does not ask of its early formation and past biography, nor does he speculate upon its future uselessness; he regards it as he finds it. So with animal vitality. We have to regard the animal as an engine, and in lieu of steam we have vitality. The engine is constructed so as to be utilised by the power of vitality, as that other engine is by the power of heat. Animals are much more economical engines than any man has made. The Creator's work is still far in advance of the work of the creature. Count Rumford showed that the amount of work done by a horse is much greater than could be obtained by employing its food as fuel for a steam-engine.

Note, also, what an economical conserving of energy there is in hibernating animals, which store up in summer that which they expend in winter in maintaining animal heat. To those who intend to offer the results of their ingenuity in the economising of fuel for the gold medals and £50 prizes offered by this Society, in December next, may be commended for especial study this property of hibernating animals. Your lecturer has no authority to make the statement, but he can with some confidence assure them that, if successful in teaching us to economise fuel as they do, they will win not only the prizes of the Society, but also the thanks of the nation.

An animal body is, indeed, a wonderful self-acting and self-regulating machine. It is a structure composed of movable parts, yet firm, and at the same time locomotive. Its hinges are well fitted with self-acting lubricators; its furnace supplies itself with fuel,

* The Cantor Lectures, delivered before the Society of Arts.

and can regulate the supply to the demand; its telegraphic communications are extensive, rapid, and need no superintendence; in its laboratory are performed experiments in the very highest departments of organic chemistry.

There are two forms of vital energy which have so much of a kinetic character that we may utilise them. Indeed, one form is self-utilised; vitality seems to have engaged its exclusive services, and whether the animal be waking or sleeping, vitality claims *all those* services from the machinery of the body which are rendered in the circulation of the blood, the digestion of the food, the operation of breathing, the propelling action of the heart. These are all motions resulting from some impressed laws, which have hitherto been hidden from our powers of research. That they continue, and that we are unconscious of them; that we cannot stop them, and even if we could by any means measure them, that we could not transfer them to any other purpose is clear without demonstration.

Therefore, since for scientific physiology the study of this form of vital energy is of paramount importance, it very naturally and properly would rank as one of the chief subjects for medical students. Indeed, the minds of physicians are necessarily often guided by circumstances to meditate upon its operation, and they are called upon to accelerate its action here and to retard it elsewhere. Hence the observant anatomist becomes, if not a kinetic, at least a static mechanic; the thoughtful physician reflects and harmonises the external evidences of these internal energies, and combining the events which fall under his notice, he deduces conclusions which link the laws of vital energies in their operations with those of the other imponderable influences which pervade all the universe.

Under such circumstances as these, Dr. Mayer, of Heilbronn, in Germany, was led to conclusions in respect to the relations between heat and work which the further investigations of others by very different processes—processes in which the energy of vitality does not enter—have established as correct.

There is another form of vital energy similar to this over which we have control, and which we employ as we please within the limits which the vital power and the construction of the apparatus through which it acts permit. This is that to which we usually give the name of "muscular energy."

The qualifying words "within the limits" are essential, for the limit is in each case a hard and fast line, and we cannot overstep it. This limit is, perhaps, more admirably arranged in the animal frame than in any construction of man's devising. Although there are hundreds of muscles, yet their names, shapes, and businesses are very varied. Throughout all these changes one remarkable principle applies: every muscle is exactly adapted to the work it is likely to be called upon to perform.

There is a principle in mathematical science called the "Principle of least action." It may be explained thus—Given an object to be accomplished, then "the principle of least action" should teach how, with the smallest quantity of material and with the least expenditure of power, that object would be done. The more the muscular system is examined under this guidance, the more we are lost in wonder how exactly every portion of the body is suited for its specific work, and for the amount of work it is likely to be called upon to discharge, and more curious still, how (in special cases) the muscle may develop in order to meet certain requirements, as, for example, the muscles in the arms of a smith, as well as other muscles. And, further, how perfectly these muscles are varied in form and construction so as to meet the requirements of their respective occupations, and, if called upon by prospective emergencies, to be ready for more than ordinary exertion. Certain muscles are so prepared for extraordinary exertion, and then relapse into their normal state, thus strictly carrying out the "principle of least action."

(To be continued).

NOTES ON THE DETERMINATION OF TITANIC ACID IN TITANIFEROUS IRON ORES, ETC.

By WILLIAM BETTEL.

I TRUST the following modification of Mr. David Forbes's process ("Select Methods in Chemical Analysis," pp. 110 to 111) for the estimation of titanic acid, may not be unacceptable to those engaged in the analysis of titanic ores:—

Fuse about 0.5 grm. of the *finely* powdered ore with 6 grms. of pure bisulphate of potash (which has been recently fused and powdered) in a platinum crucible at a gentle heat, carefully increased to redness, and continued till the mass is in tranquil fusion.

Remove from the source of heat, *allow to cool*, digest for some hours in 5 or 6 ozs. of cold distilled water—not more than 10 ozs. is to be used, as it generally causes a precipitation of some TiO_2 —filter off from a little pure white silica, dilute to 45 or 50 ozs., *add sulphurous acid until all the iron is reduced*, then boil for six hours, replacing the water as it evaporates.

The titanic acid is precipitated as a *white* powder, which is now to be filtered off, washed by decantation, a little sulphuric acid being added to the wash-water to prevent it carrying away TiO_2 in suspension. Dry, ignite, allow to cool, moisten with solution of ammoniac carbonate, re-ignite, and weigh. The titanic acid is invariably obtained as a white powder with a faint yellow tinge, if the process has been properly carried out.

I find the method of fusing with bisulphate of potash ("Select Methods," p. 125) to be preferable to all others for decomposing difficultly soluble iron ores.

CORRESPONDENCE.

AMMONIA TEST FOR DRINKING-WATER.

To the Editor of the Chemical News.

SIR,—The importance of the ammonia test for drinking-water, and the extensive use now made of it, render it desirable that it should be as accurate and as easy of application as possible. In common with others, we have had great trouble in using it, in consequence of the slowness and uncertainty of the Nessler reaction.

In a recent letter, Mr. Wanklyn attributes this to the manner of preparing the Nessler solution, chiefly to the neglect of the addition of mercurial solution at the end of the process. Although this may be the cause in some cases, it is certainly not so in all, and I desire to point out a source of difficulty which appears to have been hitherto overlooked; this is the presence of *carbonic acid* in the liquid to be tested. In a distillate, unless it has been exposed to the air for some time, this is not likely to occur, and accordingly I have frequently found a sharp reaction in the distillate, but no reaction in the comparison liquid until after a preposterously large quantity of the ammonium chloride solution had been added, or until a very long time had elapsed. Recently, examining the distilled water which gave this result, I found in each instance that there was a considerable quantity of carbonic acid present, and that, by taking fresh distilled water free from carbonic acid, a sharp and immediate reaction was obtainable. Similarly, if there be carbonic acid in the distilled water with which the ammonium chloride solution is made, there will be delay in the reaction.

The explanation is, that the carbonate, as well as other salts of ammonia, will give a reaction with Nessler's solution in extremely small quantity, but the addition of

an excess of carbonate or carbonic acid alone will redissolve the precipitate, or discharge the colour of the liquid.—I am, &c.,

F. DE CHAUMONT, M.D., Surgeon-Major.

NOTICES OF BOOKS.

Half-Yearly Compendium of Medical Science. Part IX., January, 1872. Philadelphia: S. W. Butler.

THIS compendium takes a wider scope than its English contemporary, Braithwaite's "Retrospect," and contains a large and varied amount of important matter, selected from European as well as from American authorities. If we do not quote any of its chemical notes, it is merely on account of their dating nearly two years ago, and having consequently been brought before the public through other channels. We are particularly struck with an article on the "Pathological Effects of the East Wind," which, though not coming within our ordinary scope, is profoundly suggestive, and may, perhaps, offer the key to many unsolved questions, psychological and social as well as pathological.

We notice a feature in the paging of the book which may be worth imitation in works of a similar nature. The running page of each number is at the bottom, whilst each department is paged independently at the top. Thus the work when bound resolves itself into a number of separate volumes on "Materia Medica and Therapeutics," "Clinical Medicine," &c. In the table of contents, the names of American authors are given in small capitals, those of foreign authors in Italics.

Proceedings of the American Pharmaceutical Association at the Twentieth Annual Meeting, held in Cleveland, Ohio, September, 1872. Philadelphia: Sherman and Co.

THESE "Proceedings" contain both scientific matter and important papers bearing on the drug trade, and on the status and prospects of the pharmaceutical profession in the United States. The organisation of the Association appears to us complete and efficient. There are standing committees on the drug market, on the progress of pharmacy, on adulteration and sophistication, on legislation, on infringement of stamp tax, and on a variety of other matters of importance to the profession.

Many of the papers read, though not of a character coming within the ordinary scope of our cognisance, strike us as being exceedingly valuable. Prof. Moore's strictures on certain "commercial elixirs," as being merely a fashionable way of getting stimulants into the stomachs of women and children, are quite applicable on this side of the Atlantic.

There is a lengthy paper on the manufacture of glass as applied to the make of bottles for containing chemicals. None of the forms of stopper suggested equal, in our opinion, the mushroom pattern, in which the stopper, properly so-called, terminates in a cap, concave downwards, so as entirely to protect the lip from dust. The absurdity of putting articles easily acted on by light is denounced, and a canary-yellow shade, producible by uranium, is shown to be much superior for such preparations, as cutting off the so-called chemicals rays of light.

There is some discussion on insects capable of acting as substitutes for cantharides. Here we must protest against the unscientific custom of applying the term "bug" to coleopterous insects or beetles, an error as great as the Cockneyism of calling the cockroach a black-beetle.

There are well-grounded complaints on the increasing prices of drugs and chemicals, aggravated in America by

a scale of import duties almost as vexatious as those under which our grandfathers laboured in the good old days of the younger Pitt. It is doubtless a mark of great liberality on the part of Congress that indium is admitted duty free.

We are glad to find that the efforts of American pharmacists for securing a higher educational standard in their body, and for excluding incompetent persons from the profession, are seconded by public opinion and by the legislature.

A paper on the analysis of glacial phosphoric acid of commerce shows that many samples contain as much as 10·7 per cent of soda. Arsenic in minute traces was found only in one sample.

An appendix treats of the weather observations and the storm-signal service in the United States.

We cannot conclude this brief notice without expressing our cordial sympathy with the American pharmacists in their efforts for the organisation of their profession and for the elevation of its status.

A Compendious Manual of Qualitative Chemical Analysis. By C. W. ELIOT and F. H. STORER. Revised by WM. R. NICHOLS, Professor of General Chemistry in the Massachusetts Institute of Technology. Second revised edition. New York: D. Van Nostrand.

MANUALS of chemical analysis, especially qualitative, have a strong family likeness, and their increasing number renders it difficult to say which we should prefer. In the work before us there is little to which we can object. The usual tests and the precautions to be observed in their application are carefully and clearly described.

It strikes us, however, as rather strange that of the known metallic elements twenty-two only are taken into consideration. Those omitted cannot be, as a class, pronounced either rare or unimportant. Some of them are of frequent occurrence both in natural minerals and in manufacturing products and residues. They are capable of modifying or simulating characteristic reactions, and of interfering with industrial processes. Some of them—we may instance uranium and tungsten—have their practical applications. On these grounds we are led to doubt whether their sweeping exclusion from elementary analytical manuals is altogether judicious. We would not certainly plunge the beginner into the niceties requisite for recognising the various members of the cerium group, but we submit that Messrs. Eliot, Storer, and Nichols have fallen into the opposite extreme.

Turning to the instructions given for the detection of phosphoric acid, we find it stated that the molybdate of ammonia test "can be used in presence of arsenic acid." Neither is there any caution given as regards the presence of silicic acid in the substance under examination. Yet the highest authorities have shown that both arsenic and silicic acids form, with molybdic acid, precipitates similar to that yielded by phosphoric acid under the same circumstances, and have therefore insisted on the elimination of the two former bodies as a necessary preliminary to the use of the molybdic test. It is perfectly true that the addition of a few drops of a solution of arsenic acid or of a soluble arseniate to the molybdic test-liquor does not cause, in the cold, the immediate formation of a yellow precipitate. But neither is it safe to infer the absence of phosphoric acid if a precipitate is not at once formed in a cold solution. Either prolonged standing or digestion at a gentle heat is necessary if the amount of phosphoric acid is minute. We are, therefore, compelled to pronounce this paragraph as unsatisfactory, and to suggest to the editor the propriety of its revision.

The formula given for the "magnesia" mixture used in the detection and estimation of phosphoric acid appears preferable to that of Fresenius, as being less likely to cause the precipitation of magnesian hydrate.

The appendix contains directions for the preparation of the necessary reagents, a list of apparatus, and some brief

but valuable notes on manipulation. We quote the following passage:—"Whenever a reagent is to be used, the bottle which contains it should be grasped in the right hand; the stopper should be taken out by pinching it between the first (thumb) and second or third and fourth finger of the left hand, or by pressing it between the little finger and the palm of that hand. In either case the bottle is withdrawn from the stopper, not the stopper from the bottle. Neither bottle nor stopper should be put upon the table; the stopper should be held in the left hand as long as the bottle is open. When the reagent has been poured out the bottle is immediately closed and returned to its place upon the shelves. If these apparently trifling particulars are scrupulously attended to, no stopper can ever be misplaced or soiled by contact with liquids or dirt on the table. Moreover, the label on the bottle cannot be injured by drops of the reagent, since the liquid must necessarily be poured from the back or blank side of the bottle." If students trained in such principles do not become sound, accurate chemists, the fault will be their own.

MISCELLANEOUS.

Public Analyst for Salford.—At a meeting of the Salford Town Council, held at the Town Hall, Salford, on the 6th inst., Mr. Alderman Davies moved: "That the Council be recommended to appoint Mr. Joseph Carter Bell, F.C.S., to be public analyst for the borough, and that his remuneration be by fees or allowances, as provided by the Adulteration of Food, Drugs, &c., Act, 1872, such appointment to be terminable by three months' notice in writing from either party." He said that, according to the Act of Parliament, the minimum fee of the public analyst would be 2s. 6d., while the maximum fee would be 10s. On the appointment of Dr. Tatham as medical officer of the borough, it was thought that he would undertake the duties of public analyst, but Dr. Tatham had found that his time was fully occupied with his own duties, and had expressed himself unwilling to undertake the office of public analyst. Mr. Alderman McKerrrow, in seconding the motion, said he considered the Council had been fortunate in obtaining the services of Mr. Bell, as there were few gentlemen of his qualifications who would accept the appointment without a fixed salary. The motion was passed.

Impure Water.—At a recent meeting of the Chemo-Agricultural Society of Ulster, Dr. Hodges reported the results of several analyses of the water of springs. He said that the composition of the water supplied in the districts surrounding Belfast continued to receive attention from him, and in consequence of his representations much improvement had been effected, and the use of some waters which he had found largely contaminated with sewage impurities had been abandoned. This inquiry at the present time was of especial importance. In several cases the outbreak of fever was the first thing which attracted attention to the impurity of the water used. He had formerly reported that the water supplied to the District Lunatic Asylum at Downpatrick had become polluted by sewage matters, derived from sewers which passed near the well. This cause of danger to the inmates of the establishment had now been removed; and lately he had the satisfaction of reporting that the water now supplied was of very superior quality. A water, Dr. Hodges stated, may be turbid, and deposit a sediment on standing, and be free from sewage impurities. Thus, occasionally the town water was turbid, like all waters from districts abounding in peat; but this impurity did not appear to exercise any effect injurious to health. It should, however, be removed by a more perfect system of filtration than that at present in use. Nitrogenous impurities are, however, very different from those derived from peat and soils rich in vegetable matters, and the presence in a

water of a large amount of ammonia or of albumenoid ammonia is always to be regarded as significant of danger. It is true that the large extent of land drained by streams must, in many cases, convey to the rivers from which the water supply is frequently derived, refuse matters containing nitrogenous matter in various forms, even when no sewage matter is present. But this pollution may become a cause of disease, and when wells or streams are situated in the midst of a dense population, the nitrogenous matters carried into them are especially dangerous, and their amount is usually regarded as a measure of the quality of the water and its suitability for domestic use. As an illustration of the power which we possess of preventing disease, the valuable report of Surgeon-Major De Renzy, "On the Extinction of Fever in the Millbank Prison by the Disuse of Thames Water," is most instructive, and deserves the careful consideration of the public bodies in this and other towns. It appears that the convicts in the prison previous to 1822 had been subject to an intestinal flux, which the medical officer supposed to be due to over-feeding and insufficient exercise. The dietary was altered; yet three months after an epidemic of dysentery, diarrhoea, and fever, accompanied with scurvy, began, affecting 500 convicts out of the 880 confined. In 1832 the prison suffered severely from cholera, and then some subsequent severe visitations of dysentery, fever, and cholera. The opinions of the leading scientific men of the metropolis were obtained, and means for securing ventilation, &c., were tried, but without effect. In the years from 1845 to 1854 there were 57 deaths from typhoid. The water supply was changed in August, 1854. Up to that date the water used was taken from the Thames, as it flows by the prison, purified by filtration. The new supply was from an artesian well in Trafalgar Square. It was during the severe epidemic of cholera, and there were cases of cholera in the prison at the time. Six days after the change the disease suddenly ceased, and a marked improvement took place in the health of the prison. From that period up to April, 1872, a period of nearly nineteen years, there have been only three deaths from typhoid, viz., one in 1855, one in 1860, and one in 1865. Of these, the last occurred in a convict who was suffering from the disease at the time of his admission. In the first part of 1854, and before the change of water supply, there had been three deaths from fever and two from diarrhoea. In the nineteen years since the change of supply there has been only one death from these diseases, and this change occurred while in all other respects the sanitary condition of the prison remained unaltered. As an instance of the extent to which the wells in the country may become defiled by sewage matter, Dr. Hodges gave the following analysis of water from a well at Larchfield, near Hillsborough, which had been examined for a member of the Society:—

An imperial gallon contained—	
Total solid matters	35.0 grs.
Consisting of—	
Mineral and saline matters	22.4 "
Organic and volatile matters	12.6 "
Chlorine, equal to $6\frac{1}{2}$ grs. of common salt per gallon.	
One million parts contained—	
Free ammonia	0.02 part.
Albumenoid ammonia	0.30 "

Water Supplied from Calcutta Hydrants.—In his report on the water supplied from the Calcutta hydrants during the year 1872, Dr. F. N. Macnamara says:—"Transparency has been determined by the examination of a column of water in a 2-foot tube. It was found defective on seventy days, as against eighty-six days of last year when such imperfection was noticed. Defective transparency is in the case of this water always due to the presence of very minutely divided clayey matter. This is the same stuff which is so largely present in the river-water during the rains, and is in a so finely divided state,

and is so light, that the water must be allowed to stand for at least four or five days before it clears by subsidence—filtration through several folds of filtering-paper does not remove the cloudiness. On some occasions the cloudiness became apparent in a very sudden and marked way, and was then accompanied by an increase in the organic matter dissolved in the water, but on other occasions a faint cloudiness of the water was not associated with increase of organic matter. This is a point which was particularly attended to, as there has been dispute regarding it amongst observers in England, amongst whom some have held that access of cloudiness to the water must necessarily be accompanied by an increase of organic matter. I have, however, satisfied myself that this view is an erroneous one, and that loss of transparency is not necessarily accompanied by any determinable addition to the organic matter in the filtered water. *Chlorine, Determined in the Water without Evaporation in the usual way with Solution of Nitrate of Silver, and Chromate of Potash as Indicator.*—On no day during the year has there been such increase in the quantity of the chlorine in the water as to lead to suspicion of tidal water being pumped into the reservoirs at Pultah. The largest quantity of chlorine found in the water was in the first week in May, when it reached 9.2 parts per million (equal to 1.06 grs. of chloride of sodium per gallon). The smallest quantity found was in November, when it fell to 3.9 parts per million. *Organic Matter.*—The organic matter was present in small quantity in the filtered water till the middle of September, when a great and sudden increase occurred, and the amount of organic matter continued large till the end of November, at which time it slightly diminished, and since then, up till January 31st, there has been but little, if any, improvement in the water. This is a point on which I wish to lay great stress, as in respect to it the past season contrasts most unfavourably with the corresponding one of the previous year, for about the middle of November, 1871, the water became exceedingly pure, and continued so till the end of August, 1872. Why did not a corresponding improvement occur on the termination of the past rains? I am assured that there has been no change at the works, that the processes of subsidence and filtration have been carried on in a precisely similar manner both years, while comparison of the analyses of the river-water show that it had the same characters both years during the season under consideration. There has been, indeed, more demand upon the filters in 1872 than in 1871, for, while in round numbers 49,000,000 gallons passed the filters one year, the quantity rose to 61,000,000 gallons during the next; there must therefore have more rapid filtration, and this, however brought about, must have tended to the deterioration of the water. Further, it seems to me probable that, owing to this stress put upon the filters, especially during the season of flood-water in the river, the suspended organic matter may have penetrated them farther than last year, and may be decomposing in them and adding to the soluble impurity of the water. Moreover, the condition of the settling-tanks is such that they must maintain a considerable degree of impurity in the water. Great as is the advantage in some respects of these tanks, absolutely essential as is the separation of silt which they effect to the mechanical action of the filters, there can be no doubt that they serve as reservoirs which catch and hold an immense quantity of filth, which decomposes in them, and is by-and-by given up to the water, so that the comparatively pure water of the river after the subsidence of the floods is fouled by the stuff which has been deposited in the tanks during the preceding months. But possibly another cause is at work in maintaining the impurity, and I find it in this way. Experiments made in 1871, and recorded in the last annual report, established the fact that the water, after leaving the well at Pultah, purified itself very much prior to its distribution in Calcutta, losing about one-half its organic matter, but experiments made lately show that

nothing of the kind is occurring now, and that the water as distributed in Calcutta contains little, if any, less organic matter than the water before it commences its downward journey. Possibly the flow—about 13 miles in a 42-inch iron main to the Tallah reservoir, and about 3 miles of 30-inch main from Tallah to Wellington Square—may be more rapid this year than last, and this may account in a measure for the difference I have alluded to, but I suspect that the real explanation lies in an accumulation of dirt, either in the main, or in the reservoirs at Tallah or in Wellington Square (this has been discovered at the Tallah pumping-station), which has been yielding up organic matter to the water, and thus counteracting the purification which the water should naturally experience as it flows from Pultah to Calcutta. During August the solid matter in the water was reduced by the operation of the works to one-tenth the quantity present in the water of the river, while the organic matter was reduced to one-sixth, and it was only when the accumulation of silt upon the surface of the filter beds rendered the operations of raking the sand or removal of the surface sand necessary, that the filters became less effective. On two occasions during August and October water was drawn for examination at the same hour on the same day from six hydrants in different parts of the town. The amount of organic matter and of chlorine in the water was found absolutely the same in each sample, proving also the excellency of the processes employed, for it is simply impossible that variations in the quality of the water, and in the accuracy of the manipulations, should have balanced in each case so as to yield the results obtained; I think that there is no accumulation of dirt in the street-mains, and that there is no diffusion of dirty water from the soil into them."

PATENTS.

ABRIDGMENTS OF PROVISIONAL AND COMPLETE SPECIFICATIONS.

Improvements in the treatment of sewage, and of the deposits obtained therefrom. Major-General Henry Young, Darracott Scott, C.B., Ealing, Middlesex. January 14, 1873.—No. 154. I precipitate the sewage water with quick-lime in excess in tank No. 1. The precipitate thus produced is allowed to subside, and to the effluent therefrom I add soluble salts of cheap metallic oxides, such as the oxides of iron or zinc, in sufficient quantity to precipitate in tanks No. 2 the bases of such salts.

Improvements in treating excreta and sewage matters, and in apparatus employed therein, parts of the apparatus being also applicable to the drying and charring of other matters. John Lewis Felix Target, civil engineer, Portsdown Road, Middlesex. January 15, 1873.—No. 168. According to this provisional specification, the solid excreta are mixed with a nearly equal weight of charcoal, and about 4 per cent of coal-tar or bituminous substance. The mixture is made into blocks or bricks, which, after being dried, are burnt or charred in a muffle-furnace. The vapours and volatile bodies given off from the bricks become ignited, and the products of combustion are conducted by a flue to heat the boilers of a still or other apparatus in which the urine is treated. This utilisation, for treating the urine, of the heat given off during or previous to the conversion of the solid excreta into charcoal is an important feature of the invention. The charcoal produced by the burning of the mixture of solid excreta and other substances may be subsequently used as fuel or otherwise. Improved drying houses, muffle-furnaces, distilling apparatus, and other necessary parts are described.

Improved means or arrangements for filling or feeding lamps with liquid fuel, applicable also to the filling or feeding of other apparatus used for burning such fuel. Johann Maximilian Plessner, 11, Golden Square, Middlesex. January 16, 1873.—No. 180. This invention comprises a can or receptacle for the paraffin or oil or liquid fuel, provided with injecting mechanism or other means whereby, through the agency of a tube, the paraffin or oil or fuel can be introduced into the body of the lamp (by a suitable opening therein) without interference with the wick or allowing the paraffin or oil or liquid fuel to be exposed to the action of the air.

Improvements in the purification of coal-gas. Major-General Henry Young Darracott Scott, C.B., Ealing, Middlesex. January 16, 1873.—No. 183. The object of this invention is the removal of sulphur from coal-gas by means of oxide of iron heated to redness in a suitable chamber.

An improved pavement. Robert MacNeill, Lombard Street, London. January 16, 1873.—No. 184. My said invention relates to a pavement which has a foundation of asphalt or other bituminous or tarry substance or compound, and an upper structure or surface of blocks or other suitable material,

SUPPLEMENT TO THE CHEMICAL NEWS.

VOL. XXVII. NO. 717.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Under this heading will be found an encyclopædic list of chemical papers published abroad during the past week, with abstracts of all susceptible of advantageous abridgment. The two half-yearly volumes of the CHEMICAL NEWS, with their copious indices, will, therefore, be equivalent to an English edition of the "Jahresberichte."

NOTE. All degrees of temperature are Centigrade, unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances de l'Académie des Sciences, July 28, 1873.

New Process for the Condensation of Liquefiable Matters Held in Suspension in Gases.—E. Pelouze and P. Audouin.—The authors point to the existence of tarry matters, ammoniacal water, &c., which are held in suspension in coal-gas as it issues from the retorts, and which cannot be made to deposit even at low temperatures without the aid of costly bulky apparatus. They propose a new method of condensation, which has been already practically tested, founded on the principle that the liquefaction of the globules held in suspension in gases may be obtained either by the contact of these particles with solid surfaces, or by their contact with each other. They obtained the condensation of liquids suspended in gases or vapours by the aid of a very simple apparatus, occupying little space. The gas to be purified passes by a series of narrow apertures in the form of jets, which spread themselves over a surface placed opposite. This arrangement produces a mutual contact of the molecules during their passage through the jets, the efficacy of the action being completed by the contact with the solid surface over which the tarry matter flows. A very high pressure is not needed. The apparatus may be placed either before or behind the exhaustors. The temperature—about 50°—does not interfere with the working of the apparatus. The material may be iron, earthenware, or wood. By this arrangement ammonia, sulphide of hydrogen, and sulphide of carbon may be intercepted.

Respiration of Submerged Aquatic Vegetation.—P. Schützenberger and E. Quinquand.—The method used was titration with hydrosulphite of soda, by which oxygen dissolved in 50 c.c. of water can be determined to 0.005 c.c. or to 0.1 c.c. per litre. The plants experimented upon were beer-yeast and *Elodea canadensis*. Yeast simply absorbs oxygen and produces carbonic acid. All other things being equal the intensity of respiration was alike in the dark, in diffused light, and in direct sunshine. The absorbent power is nearly nil at 10°; up to 18° it increases slowly; from that point it grows rapidly to 35°, where it reaches a maximum which is maintained up to 50°. At 60° the absorptive power is destroyed. Fresh yeast, containing 26 per cent of solid matter, absorbed per gramme and per hour—at 0°, 0.14 c.c. of oxygen; at 11°, 0.42 c.c.; at 22°, 1.2 c.c.; at 33°, 2.1 c.c.; at 40°, 2.06 c.c.; at 50°, 2.4 c.c.; and at 60°, 0.0 c.c. *Elodea canadensis*, like all plants which develop chlorophyll, has a double respiration—(1) absorption of oxygen and production of carbonic acid; (2) development of oxygen under the influence of light. The plant on being heated in water to 45° to 50° entirely loses its power of liberating

oxygen under the influence of light without its power of absorbing oxygen being affected. The latter phenomenon was found to continue in the light with the same intensity as in the dark; being the result of an independent vegetable function, parallel to the so-called diurnal respiration or disengagement of oxygen. The phenomena of absorption are similar to those displayed in the case of yeast, but about ten times less energetic. The following amounts of oxygen were liberated during one hour by 10 grms. of the plant:—

	c.c.
1. In pure water	1.0
2. Do. + 2.5 per cent of water saturated with CO ₂	13.2
3. Do. + 5.0 per cent water do. ..	20.0
4. Do. + 20 to 30 per cent do. ..	13.0
5. Do. + 40 per cent do. ..	10.0
6. Water saturated with CO ₂ ..	3.0

On leaving an excess of the plant submerged in the sunlight for an hour or two we obtained a liquid supersaturated with oxygen, containing at 35° as much as 20 c.c. of oxygen per litre. This water, when removed from the plant, lost its excess of oxygen with remarkable slowness.

Berichte der Deutschen Chemischen Gesellschaft zu Berlin, July 28, 1873.

Action of Formiate of Soda upon Benzoic Acid.—F. v. Richter.—On fusion hydrogen is given off, and the carboxyl groups as they are set at liberty combine partly to form oxalic acid, and in part they act substitutionally. In presence of benzoate of potassa dicarbonic acids are formed—

Isomeric Series of the Benzol Derivatives.—V. v. Richter.—A theoretical paper. The author concludes that the constitution of the benzol derivatives is not so certainly established as many chemists assume.

New Constituent of Urine.—F. Baumstark.—The substance in question was found first in the urine of a dog fed with benzoic acid, then in icteric, and finally in normal human urine. Its composition corresponds to the formula $C_3H_3N_2O$. It crystallises in white columns like those of hippuric acid, which melt at 250°, and if heated on platinum foil give off dense white vapours of a peculiar odour. If heated in a narrow tube they yield a combustible gas, which turns litmus blue and smells of ethylamin. The crystals are readily soluble in hot water, sparingly in cold water, insoluble in absolute alcohol and in ether. The new compound forms soluble salts with acids, and does not combine with bases; the solution is precipitated by the nitrate of silver. On treatment with nitrous acid, lactic acid—whose very soluble zinc salts contains 12.1 per cent of crystalline water: it is, therefore, the so-called lactic acid of flesh.

On Chrysin and its Haloid Derivatives.—J. Piccard.—Some years ago the author discovered chrysin—a well characterised yellow colouring matter in the buds of the poplar. (*Bolley's Schweitz. Polyt. Zeitschrift*, vol. ix., p. 137, 1864.) He now enters upon an examination of its properties and its combinations. Chrysin is composed of—

Carbon	70.86
Hydrogen	3.95
Oxygen	25.19
	100.00

corresponding to the formula $C_{15}H_{10}O_4$. The author has formed and examined its bromide, iodide, chloride, and nitro compounds, and considers it a homologue of alizarin and frangulinic acid.

Certain Constituents of Poplar Buds.—J. Piccard.—Along with chrysin the author has come upon three ot'

bodies—the ethereal oil of poplar, C_3H_8 ; a mixture of salicin, papulin, and teuchochrysin, $C_{16}H_{12}O_4$, a higher homologue of chrysin.

Action of Perchloride of Phosphorus upon Pyruvic Acid.—C. Böttiger.—The reaction is violent; on its completion a clear pungent liquid passed over at about 55° to 60° ; which, when mixed with alcohol, gave off an odour of acetic ether. Large quantities of C_2H_5Cl , and of carbonic acid are given off, whilst a dark coloured syrup remains behind containing Climenko's ether. The author appends a preliminary announcement of a new acid obtained from the pyruvic acid.

Chlorinated Derivatives of Aceton.—Albert Theegarten.—The author obtains dichloracetone by the action of chlorine upon acetone.

Hygroscopicity of the Monophosphate of Calcium.—K. Birnbaum.—The author finds that a portion of pure monophosphate, which—after being dried over sulphuric acid—weighed 1.339 grms. when exposed to the air of the laboratory and weighed daily fluctuated from 1.478 to 1.504 grms. If placed over water the weight rose in three days to 1.876; and on being again exposed freely to the air for three days it fell to 1.501. The same phenomenon, though on a smaller scale, may be observed with superphosphate. By the variable amount of water taken up the percentage of soluble phosphate will be made to fluctuate.

Action of Anhydrous Acetic Acid upon Rhodan-Ammonium.—M. Nencki and W. Leppert.—The authors obtained by this reaction the acid acetytic ether of the bibasic persulpho-cyanic acid— $C_2H(C_2H_3O)N_2S_3$.

On Benzyl-toluol.—M. Plaseuda and Th. Zincke.—By oxidising benzyl-toluol with bichromate of potassa and sulphuric acid, the authors obtain benzyl-benzoic acid, and an isomeric body to which they give the preliminary name β -benzol-benzoic acid. This acid crystallises from hot water, in which it is considerably more soluble than the α -acid, in long and broad needles, consisting of aggregations of prismatic crystals. Along with the acids were also formed a hydrocarbon and a keton.

Commercial and the Pure Isobutylic Aldehyd and Isobutylic Alcohol.—G. A. Barbaglia.—The author concludes that the isobutyl-aldehyd, obtained from the Kahlbaum Works (which he had employed in some previous experiments), contains large quantities of acetone, and that the isobutylic alcohol is contaminated with various foreign substances, probably with a considerable amount of isopropyl alcohol. Hitherto no industrial process is known for the preparation of pure isobutylic alcohol, and isobutylic aldehyd.

On Oil of Citron.—A. Oppenheim.—A hypothetical paper. The author pronounces American oil of turpentine and the oil of citron to be both hydromethyl-isopropyl-benzols of the para series.

Critique on the Methods for the Analysis of Water.—Ferd. Tiemann.—(Continuation.)—*Determination of Sulphuric Acid.*—(1). Gravimetric Method.—The amount of sulphuric acid in a natural water can be easily and accurately determined by precipitation with chloride of barium and weighing. The results of this process, which was once considered the most accurate of all gravimetric methods, may readily become inaccurate if the precipitation of the sulphuric acid is performed in a too concentrated solution, and if a too strong solution of chloride of barium be employed. The presence of large amounts of foreign matter, especially alkalies, nitrates, &c., has a disturbing influence, as portions of them are carried down with the precipitate. Finkener even declares that the precipitate is never a perfectly pure sulphate of baryta. In the case of a natural water, however, the circumstances are especially favourable. If the sulphuric acid is thrown down from the boiling water, slightly acidulated with hydrochloric acid, with a very dilute hot solution of baric chloride—using

the further precaution to add first a little of the precipitant, and afterwards a not too large excess—and if the precipitate is allowed time to deposit without filtration, the results may be considered almost absolutely accurate. The only objection is the amount of time required; whence the following methods have been proposed by Weldenstein, and by Boutron and Boudet. Weldenstein precipitates the sulphuric acid by adding an excess of chloride of barium solution of a known strength, and titrating the excess with a neutral solution of chromate of potassa. As large amounts of carbonate of lime have a disturbing influence the water should be rendered acid at the beginning of the experiment, and neutralised again before the addition of the chromate. It is better to boil the water previously, and make it up to its original bulk with distilled water before the determination. The author finds that boiling does not cause the precipitation of sulphate of lime if the loss by evaporation is constantly approximately replaced by distilled water. There is, in Weldenstein's original method, a difficulty in finding the exact end of the reaction. To obviate this 100 c.c. of the water, previously boiled and made up to its original bulk, are heated to boiling in a flask marked at 150 c.c. and 10 c.c., or if much sulphuric acid is present, 15 to 20 c.c. of a solution of chloride of barium containing 1-10th of an equivalent per litre. After boiling for a few minutes, such a quantity of a corresponding solution of neutral chromate of potassa is added, that when the precipitate settles the supernatant liquid appears faintly but distinctly yellow. When the whole is cold, which is accelerated by setting the flask in cold water, the flask is filled up to the mark with distilled water, the contents shaken and filtered through an unmoistened filter. 100 c.c. of the filtrate are placed in a narrow cylinder of colourless glass, in which the liquid may stand at the depth of 15 to 20 centimetres. In a similar cylinder 100 c.c. of distilled water are then mixed with so much of the standard chromate solution that both exhibit the same tone of colour. The shades produced by 0.1 to 0.6 c.c. of the 1-10th chromate solution can be clearly distinguished. The amount of the chromate added in excess as thus ascertained, multiplied by $\frac{1}{2}$, is deducted from the amount of this solution which has been added to the water under examination. From the difference between the remaining c.c. of chromate, and the c.c. of chloride of barium consumed, the amount of sulphuric acid in the water is readily calculated. In Boutron and Boudet's method the sulphuric acid is thrown down from the boiled water—whose permanent hardness is known—by solution of baric chloride in excess, the value of which is adjusted to the soap liquor. The whole is filtered after the precipitate has settled, and the remaining hardness of the filtrate is determined by the soap-test. If to the "permanent hardness" of the water we add the degrees of hardness corresponding to the baric chloride solution added, and from the sum deduct the hardness of the filtrate, we obtain a value from which the amount of sulphuric acid in the water may be readily calculated. The author proposes the following modification of this method:—100 c.c. of the water previously boiled are heated to boiling in a flask marked at 150 c.c., and mixed in slight excess with a solution of baric chloride, every c.c. of which corresponds to a German degree of hardness. After the precipitate has settled, and the liquid has cooled, the flask is filled up to the mark with distilled water filtered through an unmoistened filter, and the residual hardness is determined in 100 c.c. of the filtrate. In connection with the determination of sulphuric acid the author adds some observations which he has made on grouping together the figures found in the analysis of waters. The permanent hardness of the water, its percentage of sulphuric acid, chlorine, nitric acid, alkalies, and ammonia are here brought into question. In drawing out the results of an analysis of water it is customary to assign the chloride to the alkalies; the remainder of which are calculated as sulphates, whilst the excess of sulphuric acid is allotted to lime and magnesia, as also

the residue of the nitric acid after the ammonia is satisfied. This arrangement is by no means satisfactory with the subsoil waters of populous places. If the supposition on which the above-mentioned arrangements are founded were correct, the total amount of the fixed bases, and the ammonia which is required to saturate the sulphuric, hydrochloric, and nitric acids present, would stand in a definite relation to the ascertained permanent hardness of the water. If we consider the well-known fact that the bicarbonate of lime is not perfectly removed by boiling; and that even after expulsion of all the so-called half-combined carbonic acid 3.5 of carbonate of lime remains dissolved in 100,000 of water; which consequently make up 2 German degrees of the permanent hardness of every water originally containing bicarbonate of lime. Then on the assumption that the above-mentioned grouping of the several constituents is correct, the permanent hardness of a water may be readily calculated if its percentage of alkalies, ammonia, sulphuric acid, hydrochloric acid, and nitric acid is known. Now the more impure the water, the less do the found and the calculated degrees of hardness agree. It appears that in such cases the excess of water must be combined with organic bases. It is very probable that between ammonia and the original nitrogenous organic bodies there exists a series of transition products possessing more or less decidedly basic properties. If nitric acid exists partially at least combined with organic bases the remarkable phenomenon is explained that spring waters, rich in nitric acid, contain—almost without exception—large amounts of organic matter. But whilst it is highly probable that the nitric acid of polluted wells is not, generally speaking, present as a lime or magnesium salt, nitrates and chlorides of these metals may have found their way into such, or, indeed, into any natural water. A great discrepancy between the amount of sulphuric acid as found, and as calculated from the permanent hardness of a water—in other words, a considerable amount of sulphate of potassa—may be considered as one of the indications of pollution.

Certain Substances of the Camphor Group, and on the Constitution of Camphor.—Aug. Kekulé.—A hypothetical dissertation on the true formulæ of camphor, of borneol, campholic acid, campheric acid, carvol, and carvacrol.

Preparation of Oxy-cymol from Camphor.—A. Fleischer and Aug. Kekulé.—The authors obtain oxy-cymol from camphor by cobination with iodine.

Derivatives of Cymol.—Fr. Landolph.—The author has studied especially the nitro derivatives of camphor-cymol, and obtained α -mononitro-cymol, $C_{10}H_{13}(NO_2)$.

Identity of the Cymols from Camphor, Ptychotis Oil, and Thymol, and on a Second Thiocymol.—F. Fittier.—The author considers the identity of these cymols demonstrated by his experiments. The new thiocymol has the composition $C_{10}H_{14}S$.

Action of Perchloride of Phosphorus upon Phenol-Parasulphonic Acid.—Aug. Kekulé.—The products of the reaction, which pass over between 60° and 120° , consist only of thionylchloride and oxychloride of phosphorus. At 265° to 267° a peculiar oil is separated out, whilst the intermediate products, when decomposed with water, yield a large quantity of bichlorbenzol.

Isomeric α and β Derivatives of Naphthalin.—C. Liebermann and Aug. Dittler.—Nitro-naphthylamin, $C_{10}H_6NH_2NO_2$, fuses at 191° , is sparingly soluble in water, readily in alcohol, and dyes wool an intense picric yellow. It does not form salts. It is isomeric with Beilstein's nitro-naphthylamin, which melts at 118° to 119° .

Decomposition of Rosanilin by Water.—C. Liebermann.—The author had formerly shown that when rosanilin is heated to temperatures above 240° along with water the atoms of nitrogen are successively eliminated as ammonia and replaced with equivalent amounts of water. He has since succeeded in obtaining the final

product free from nitrogen. It has nothing in common with rosolic or hydrosolic acid. It crystallises in colourless lancet-shaped leaflets. The compound fuses at 200° , and dissolves in dilute alkalies without colour. In water with soda-amalgam it dissolves with a transient red colour, like that which the anthrachinons and other chinons display under similar reducing reactions.

Dibenzyl-Disulpho Acid.—R. Kade.—The composition of this acid is $C_{14}H_{14}(SO_3)_2 + 5H_2O$. The author has examined the lead and barium salts.

On Dipropargyl.—Louis Henry.—A lengthy paper on the compound C_6H_6 , with its reactions and combinations.

Gazzetta Chimica Italiana, Anno III., Fascicolo V. e VI., July 30, 1873.

Researches on Santonin.—S. Cannizzaro and F. Sestini.—The authors have obtained a substance composed of $C_{15}H_{20}O_4$, to which they give the name santonin acid. It is colourless, sparingly soluble in cold, but more freely in hot water, from which it is deposited on cooling in fine prismatic crystals. It is readily soluble in ether, and still more so in alcohol, also in chloroform, and in glacial acetic acid. It melts to a colourless liquid at 161° to 163° . On treatment with alcohol and caustic potassa it does not produce that fine red-violet colouration which characterises santonine. Its acid reaction is very decided, and it decomposes warm solutions of carbonates with brisk effervescence. The authors have further studied the santonates of sodium and barium, and the behaviour of the new acid with bromine and nascent hydrogen.

New Researches on Benzylated Phenol.—E. Paterno and M. Filetti.—In a former memoir (*Gazz. Chim.*, tome iii., p. 121) the authors described the preparation of anthracen from the action of chloride of benzyl upon phenol in presence of zinc, and announced the view that this hydrocarbon owed its origin to a transformation of benzylated phenol. Continuing the study of this substance they found that it can, in fact, furnish anthracen by a very simple reaction when distilled with anhydrous phosphoric acid.

Monochloride of Acetyl.—E. Paterno and G. Mazzara. Monochloride of acetyl when pure is a liquid perfectly transparent, and of a most pleasing odour, and sweetish, burning taste. Its boiling-point is 156.8° , and its sp. gr. is at 0° 1.0418, at 26.3° 1.0146, and at 99.9° 0.9315.

Chemical Analysis of Various Wines from the District of Verona.—Prof. Giovanni dal Sie.—A laborious contribution to agricultural chemistry, showing in a tabular form the age of 100 samples of wine, the names of the grower, their physical characters, their locality, the quality of the soil, the kind of grape, the percentage of alcohol, both by weight and volume, the proportion of residue on evaporating at 120° , the ash, the water, and the recorded character of fermentation.

Dry Distillation of the Formiate of Lime.—A. Lieben and E. Paterno.—Among the products obtained the authors especially notice methylic alcohol.

The Combustible Fossils of the Province of Siena Applied to Industrial Uses.—G. Campani and C. Giannetti.—("Memoire della R. Accademia der Fisiocritici di Siena, 1873.") An analysis of three samples of lignite.

Moniteur Scientifique, du Dr. Quesneville, August, 1873.

Researches of the Polymers of Morphia and their Derivatives.—Ludwig Mayer and C. R. A. Wright.—A translation from English sources.

New Procedures for the Manufacture of Coal-Gas.—T. Wills.—A translation from the *Journal of the Society of Arts*.

Theory of Tanning.—M. A. Reimer.—A continuation of the elaborate paper which we have already noticed.

The Regeneration and Restoration of Oil Paintings by Pettenkofer's Method. (A report presented to the Industrial Society of Mulhouse.)—M. Fr. Goppelsröder.—Radlkofer has proved that the deterioration of paintings is not due, as was suspected, to organic formations. It is evident that colours, even the most stable, cannot preserve their original shade and brightness, except on condition that the drying oil, which has interpenetrated them, and in which they are in a manner suspended, retains its optical properties. The most important part of the oils employed by artists is linoleine. This body not being procurable in a state of purity, painters are obliged to use linseed oil in which it is present in the proportion of 80 per cent; or propyl oil, of which it constitutes 75 per cent. Linoleine, originally liquid, solidifies by oxidation without decrease in bulk, but increasing in weight to the extent of 10 per cent. It is then a hard transparent mass, which encloses the colours and the other portions of the oil. It is because linoleine acquires on exposure to the air a consistence invariable at the different temperatures of the atmosphere that the portions of colour when the painting is dry can no longer be displaced, whether by a gentle pressure, or by the fatty and volatile oils and varnishes. As there are, everywhere in the world, atomic and molecular movement, changes physical and chemical take place in paintings. These changes occur more frequently in the oil than in the colour. The colours containing the least oil change most. Pettenkofer's method of restoring pictures is very simple. He makes first a trial on a small scale by means of a round paste-board box, plastered within with strong glue, and the bottom of which is lined with flannel moistened with alcohol at 80 per cent. The box is inverted and placed upon the picture. The part thus treated serves as a guide for the operations on a larger scale. In the latter a box is employed, the bottom of which is lined with flannel, whilst the picture is fixed to the lid. Pettenkofer employs also balsam of copaiba, which is often applied with success to the back of the picture.

On Alimentary Substances in General, and on the Extract of Meat in Particular, Regarded as the Food of Man.—Dr. Max von Pettenkofer.—We extract from this valuable paper the following significant passage:—"It is only a short time ago that it was customary in physiology to speak of a superfluous or luxurious consumption. According to certain physiologists as long as the body is able to perform its functions, even though suffering from hunger, to take more food was luxury. But Bischoff and Voit fully demonstrated by their experiments on nutrition that the result of a nourishment so restricted is a state of want—a continual famine incompatible, in the long run, with the normal conditions of life. The body has need of a certain well-being—of a small excess of nourishment in order to preserve its strength and vigour. What just prevents death from hunger is not sufficient. It is as if we were to restrain the organism from producing any more heat than suffices to prevent death from cold, under pretext that all beyond this limit was superfluity and luxury."

The Farina of Meat and the Salts of Meat.—Dr. Dunkelsberg.—The author points out the importance of mineral salts in the nutrition of animals.

Revue Scientifique de la France et de l'Etranger,
August 16, 1873.

This number contains no chemical matter.

Revue des Deux Mondes, July 15, 1873.

The New Explosives.—M. F. Papillon.—The author estimates the pressure exerted upon a cannon-ball by common gunpowder at 5000 atmospheres. The temperature produced by its ignition he considers to be 2500°. Berthelot's table of the relative heats, volumes of gas, and explosive forces obtained by means of gunpowder,

chlorate powder, gun-cotton, picric acid, and nitro-glycerine is then quoted. (We suspect that Berthelot must have used in his experiments gun-cotton weakened by a considerable amount of dinitro-cellulose.) He gives the highest rank to liquefied protoxide of nitrogen, mixed with ether or other liquid carbides.

Reimann's Färber Zeitung, No. 27, 1873.

This number contains receipts for a scarlet on cloth, in which the following mordant or "spirit" is employed:—12 lbs. bichloride of tin, and 12 lbs. tin crystals dissolved in water enough to form a solution at 36° B. Further, for a yellowish green on cloth, a "May green," a golden yellow; for scarlet, rose, and salmon on woollen yarn, to be produced in succession from the same bath; for a rose shade on wool, for a lemon yellow; a fine black for silk waste: a fine logwood blue (a substitute for a vat blue) upon cotton-wool, and for finishing velvets. The following process for dyeing linen yarn with aniline colours has been patented by Hainisch, of Vienna. The yarn is worked alternately in the two following solutions:—(1) 1 part tannin in 500 parts of water. (2) 1 part glycerin in 32 parts of water, to which egg albumen is added. The yarn remains in each about ten minutes. For very delicate shades No. 1 is omitted. (The only novelty in this patent is its astonishing audacity.)

No. 28, 1873.

This number contains a notice of the Vienna Exhibition from a colourist's point of view, followed by receipts for an alkali blue on woollen yarn or piece goods; for a new alkali on flannel; for light and dark drab-grey on woollen yarn; heavy black on wool; blue-black, bright blue, sandal-brown, and red-brown on the same; instructions for finishing off velvet after dyeing; grey on leather; coralline-red on cotton; and mat finish for lining-cottons. The editor criticises Lauth's assumption that the dimethyl-anilin used in the manufacture of violet-de-Paris (methyl violet) is perfectly free from toluidin compounds. MM. Lloyd and Green propose to prepare an oil for mordanting yarn and cloth to be dyed Turkey red, by adding, to 1 part of oil, 14 parts of a solution of bleaching soda (hypochlorite of soda at 31° Twaddell). The goods prepared with this emulsion are fit for dyeing sooner than if treated in the ordinary manner.

Revue Hebdomadaire de Chimie Scientifique et Industrielle
par Ch. Mène, May 15, 1873.

This number contains an account of apparatus for heating wines (Pasteur's process), a description of some artistic earthenware, and of a new continuous press for the sugar manufacture. The process of Zettnow for purifying hydrochloric acid is as follows:—The crude acid of sp. gr. 1.6 (that sold in this country rarely exceeds 1.17), and free from iron, is mixed with a little chlorine-water and chloride of lime, to oxidise sulphurous acid if present. It is then stirred up with commercial protochloride of tin (tin crystals), in the proportion of 50 grms. to 10 to 12 kilos. of raw acid, or nearly 2 ounces to 2 gallons. The separation of arsenic and the clarification of the acid are complete after twenty-four hours rest at the temperature of 30° to 35°, and after one to four days at ordinary temperatures. It is then distilled, with the addition of a little common salt and a little sand to regulate the ebullition. The method of Engel, which depends on the use of the hypophosphate of potash, has been already noticed.

Artificial Marble.—G. A. Frear.—This invention consists in the employment of a solution of sulphate and chloride of zinc, sugar of lead, alum, and common salt, mixed in suitable proportions, and dissolved in water to agglomerate the particles of powdered silica, alumina, marble cement, hydraulic cement, sulphate of lime, baryta, and other earthy substances except carbonate of lime.

THE CHEMICAL NEWS.

VOL. XXVIII. No. 718.

SPECIFIC GRAVITY OF RUBIES AND SAPPHIRES.

By GRENVILLE WILLIAMS, F.R.S.

IN my paper "Researches on Emeralds and Beryls,"* I stated that the artificial rubies made by me by Gaudin's process, had a lower specific gravity than that of the true ruby. I there assumed the density of the ruby to be 3.53, on the authority of Brisson,† and that of the sapphire as 3.56, according to Muschenbroek.‡ Having occasion, in extending my experiments on the subject, to take the specific gravity of several rubies and sapphires, I found their density to be very much higher than the numbers given in Gmelin's "Chemistry." On referring to other works,|| I found the numbers given in them to be generally between 3.9 and 4.0; Professor Church also found a blue sapphire to have a density of 3.979, and a yellow one 4.030. My own determinations, made upon very fine stones, gave me for rubies 3.95, and for sapphires 3.98. Assuming 3.95 as the average specific gravity of the ruby, it will be seen that Gaudin's rubies as first made by me were 0.5 lower in density than the native ruby, instead of 0.08 as given in my former communication. I have, however, recently succeeded in preparing some fresh specimens of artificial rubies by the same process, but with a higher density, namely 3.7; this number is only 0.25 lower than the native ruby, and I think it probable that the true density of the ruby might be attained if the frothing, which takes place to a greater or less degree under the intense heat of the oxyhydrogen blowpipe, could be completely avoided.

THE CHEMICAL CONSTITUTION OF SUCCINIC, MALIC, AND TARTARIC ACIDS, CRITICALLY EXAMINED AND INTERPRETED FROM THE STAND-POINT OF THE "TYPO-NUCLEUS" THEORY.

By OTTO RICHTER, Ph.D.

(Concluded from p. 91).

PART III.

On the Principal Molecular Changes that Accompany the Artificial Production of the Water-Salts of Succinic, Malic, and Tartaric Acids in our Laboratories.

UNDER this head a number of interesting cases have fallen under my notice, out of which I shall select the following four:—The first case refers to the artificial production of the ortho- and iso-succinate, which, according to Byk and Wichelhaus, may be got by boiling the corresponding varieties of cyan-propionate with potash ley. The second case refers to the artificial production of the ortho-succinate, which, according to Simpson, may be got by boiling the di-cyanide of ethylen with potash ley. The third case refers to the artificial production of the ortho-tartrate (the inactive form), which, according to Debus, is generated on treating a mixture of glyoxal and hydrocyanic acid with solution of potash. The fourth case refers to the artificial production of the ortho-tartrate (the

racemic variety) which, according to Heintz, is found among the products of oxidation of the ordinary glycerate of water.

The proper discussion of the first case renders it incumbent on me to examine more minutely into the chemical origin and constitution of the nitrogenous substances that form the basis of these experiments.

In the first place, as regards the cyan-propionate. This compound, which gives rise to the ortho-succinate, may be prepared by the following method:—When ethylen, $2H_2C_2$, is exposed to the action of phosgen gas, $2C_2Cl_2O_2$, the product of their direct union is the chlor-propionyl chloride, and the molecular changes attending its formation are believed to be as follows:—In the first stage, the phosgen splits up into carbonic oxide and free chlorine, which, by an action strictly analogous to that of oxygen (*vide* Part I.), effects the conversion of the ethylen into the biatomic dichloride of ethylen—

In the second stage, the methylen adjunct of the latter parts with its 2 mols. of hydrogen, which are oxidised into 2 mols. of water at the expense of the carbonic oxide, but these 2 water mols., instead of being eliminated, are instantly brought to bear upon the residual carbon nucleus, so as to give birth to a mol. of formite of water. In the third stage, the formous acid constituent of this latter enters into chemical union with the dehydrogenated dichloride of ethylen, with production of the chloride in question, the chemical constitution of which is, therefore, expressed by the formula—

In contact with water, this substance becomes speedily decomposed into hydrochloric acid and the chlor-propionate—

which, by treatment with cyanide of potassium, &c., becomes finally converted into the cyan-propionate—

In the second place, as regards the iso-cyan-propionate. This compound, which gives rise to the iso-succinate, may be prepared by the following method:—When 1 mol. of iso-lactate (ordinary lactate) of lime—

is acted upon by 2 mols. of perchloride of phosphorus, it becomes transformed into the iso-chlor-propionyl chloride—

In contact with water, this substance readily decomposes into hydrochloric acid and the iso-chlor-propionate—

which, by treatment with cyanide of potassium, &c., becomes finally converted into the iso-cyan-propionate—

Let us further contemplate the molecular changes, which attend the conversion of these two isomeric varieties of cyan-propionate into the corresponding succinates. The copious evolution of ammonia in both cases clearly shows, that the alkali has effected the decomposition of these bodies into the lactate (so-called para-lactate, and identical with the glyceric aldehyd of Socoloff) and into the iso-lactate, while the liberated hydrocyanic acid has been made to resolve itself into ammonia and formate of water.

* *Proc. Roy. Soc.*, 1873, No. 145, p. 409.

† Gmelin's "Chemistry," Cavendish Society's translation, vol. iii., p. 305.

‡ *Loc. cit.*

§ "Brooks and Miller," "Watts's Chem. Dict.," "Rammelsberg," &c.

Before proceeding farther, and with the view of still more fully confirming my conception of the molecular structure of lactic and iso-lactic acids, I have deemed it advisable to interlace an analysis of the principal molecular changes which accompany the artificial production of these two isomerides. I allude to the beautiful synthetical processes, devised by Wislicenus and Lippmann, whereby, according to the former chemist, ethylen cyan-hydrate—

is converted by ebullition with potash into a salt of iso-lactic acid, while, according to the latter chemist, ethylen cyan-hydrate—

is transformed under similar circumstances into lactic acid. Now, on the principles which guide me in the interpretation of chemical phenomena, the ethylen cyan-hydrate ought to give rise first of all to the intermediate product—

which, through the loss of 2 mols. of water, caused by the splitting up of the colligated formylic alcohol, and the coalescence of the liberated formen with the methylen adjunct, changes afterwards into the iso-lactate, whereas the ethylen cyan-hydrate ought to furnish the lactate directly—that is, without formation of an intermediate product—whose formula would be—

I have, indeed, good grounds for affirming, that the kind of molecular arrangement implied by this latter formula, whereby an olefine-begotten polyatomic alcohol is made to discharge the functions of a halogen adjunct, is a chemical incongruity, but that the obstacle to chemical union is removed by the conversion of that alcohol into the corresponding de-alcohol.

Reverting, again, to the intermediate product preceding the formation of the iso-lactate, a remarkable and highly instructive contrast is brought to light by the following train of reasoning:—Observe, first, that the colligated alcohol of that product is the mono-acid, but still biatomic ethylen glycol or glycolic alcohol, while the colligated alcohol of the other and, as I believe, impracticable transition product, is the biacid and biatomic ethylen glycol. Observe, in the second place, that if in the above reaction the methylen adjunct of the glycolic alcohol had experienced, at the expense of the associated formic acid principal, a water-producing process of dehydrogenation, similar to what the same adjunct is supposed to have undergone in the ethylen glycol, the resulting compound ought to be constituted according to the formula—

which shows it to be a new isomeride of lactate of water, of the real occurrence of which I myself have not the slightest doubt. But, considering that the actual product obtained is the iso-lactate of water, whose formula rests upon the concordant testimony of a great variety of analyses, the conclusion seems to me inevitable, that the typical metamorphosis, which the ethylen-glycol has experienced in the act of passing into the isomeric glycolic alcohol, is sufficient to protect the methylen adjunct against the rigorous enforcement of a law, which demands the unconditional surrender of two hydrogen molecules on the part of the olefine adjunct of a given mono- or poly-atomic alcohol, before it can be admitted into chemical fellowship with a given acid principal.

This subject may be fitly concluded by appending a list of all the theoretically-possible isomerides of lactate of water, several of which have now been obtained in a state of isolation.

Table of the Theoretically-possible Isomerides of Lactate of Water.

Let us now, after this somewhat lengthy, but, I trust, not unwelcome digression, resume our inquiry into the nature of the molecular changes which accompany the artificial production of the succinate and iso-succinate at the point where it was said that the action of the alkali upon the two varieties of cyan-propionate had given rise to two varieties of lactate, besides ammonia and formate of water. In the second stage, the formic acid constituent of this water-salt unites as ally with the formous acid principal of the lactate on the one hand, and with the formic acid principal of the iso-lactate on the other hand. The resulting compounds are, therefore, in the former case a bibasic meta water-salt—

The third stage is characterised by the splitting up of these two isomeric water-salts into 2 molecules of water and the corresponding meta-anhydrides, which, by the method of ortho-genesis, are finally transformed, the one into the ortho-succinate—

It will be seen on comparison, that these two formulae agree completely with those I have already, but on different grounds, been brought to regard as the true exponents of the chemical constitution of the two isomerides in question.

Let us now examine into the second case, which refers to the artificial production of the ortho-succinate from the dicyanide of ethylen, the chemical constitution of which is expressed by the formula—

It is clear that the formation of this latter compound from the dichloride of ethylen must be preceded by an intermediate product—

which, by treatment with potash ley, ought to furnish the above-mentioned chlor-propionate; while, under the same circumstances, the dicyanide ought to give rise, in the

first instance, to the above-mentioned cyan-propionate, for the rationale of whose conversion into the ortho-succinate it is, therefore, sufficient to refer the reader to the explanations given under the head of that compound.

The third case has for its object the artificial production of the ortho-tartrate of water* (the optically-inactive variety), the proper comprehension of which necessitates, however, a previous acquaintance with the molecular structure of the so-called glyoxal. According to my researches, this aldehyd-like substance is the lowest acid heterologue of an organic family group, whose unknown parent alcohol is represented by the formula—

The following scheme exhibits two closely related organic family groups, headed by their respective parent alcohols, and so arranged as to illustrate the complete parallelism of the two series :—

First Family Group of Heterologues.

Second Family Group of Heterologues.

N.B.—It deserves to be specially noticed, that the glyoxalate, as well as the para-oxalate previously alluded to, are bimeric modifications of the ordinary oxalate.

With the aid of this scheme, the whole process may now be explained in the following terms :—In the first stage, the glyoxalite becomes converted into the glycolite, the 2 molecules of hydrogen required for that purpose being, as usual, derived from 2 water molecules, whose oxygen serves to transform into a molecule of formate one of the 2 molecules of formate that were generated by the action of the alkali on the two accessory hydrocyanic acid molecules, while the other molecule of formate of water enters into chemical union with the freshly-formed glycolite. The product of this union, viz., the bibasic meta-glycerate—

merges afterwards into the isomeric modification of the monobasic glycerate, but in the act of doing so an opportunity is afforded to the acid constituent of the aforesaid formate of linking itself to the formic acid principal of

* The reader will bear in mind, that in my system all variations in the optical properties of a given molecule, so far from being due to differences of molecular grouping, are held to depend entirely and exclusively on the symmetrical or unsymmetrical distribution of the atomic vibratory movements around the three principal crystallographic axes of that molecule.

the glycerate. It will be seen that the resulting bibasic meta water-salt—

is absolutely identical with the transition product encountered in my analysis of the slow and gradual oxidation of the butylen-erythrol; it will, therefore, agree with the latter in resolving itself into 2 molecules of water and the ortho-tartrate in question. The fourth, and last, case has for its theme the artificial production of the ortho-tartrate from the ordinary glycerate. According to Heintz, the oxidation of this compound gives rise, amongst others, to the water-salts of formic, glycolic, glycolic, and tartaric acids, while carbonic acid is given off. The simultaneous appearance of these substances is easily accounted for on the hypothesis that the monobasic glycerate, after merging into the isomeric form of the bibasic meta-glycerate, splits up into 2 molecules of water and the tartronate, which soon resolves itself into carbonic acid and the glycolate, whence the glycolate is finally obtained by the union of the latter with 2 molecules of oxygen. In the next stage, the glycolate breaks up into the formic alcohol, which is speedily oxidised into the formate and into the formate, the acid constituent of which unites as ally with the formic acid constituent of the meta-glycerate, while it is in the act of re-assuming the monobasic form of grouping. Hence the resulting combination will be expressed by the formula—

which is again, as in the preceding case, absolutely identical with that remarkable transition product which was shown to be the immediate precursor and originator of the ortho-tartrate under consideration.

It cannot be denied, that the synthetical formation of organic compounds belonging to that distinguished family circle, which owns the tartrate for one of its most highly oxidised acid heterologues, is a fact of the deepest import and significance; and certainly, when I consider the great compactness, cogency, and coherence which competent judges will do me the justice of enumerating among the commendable qualities of my peculiar method of reasoning, I would fain persuade myself that my researches have revealed the true *modus operandi*, according to which the carbon-nuclei of one, two, or more molecules of hydrocyanic acid, originally introduced into a given molecule as non-essential elements, or co-existing in the same solution, and in close proximity to that molecule, may become permanently incorporated therein as essential elements. The reader is no doubt aware that several curious and interesting cases of this kind have recently been put on record, among which I may mention the artificial production of the ortho-pyrotartrate from the dicyanide of propylen, the iso-pyrotartrate from the iso-cyan-butyrates, and the carballylate from the tricyanide of allyl. A full discussion of these and other analogous cases is reserved for my paper "On the Chemical Constitution of Citric Acid and its numerous Derivatives," where I hope still more emphatically and conclusively to demonstrate the general soundness and validity of this entirely novel, but as yet practically untested, section of my "typo-nucleus" theory.

It is now time to take temporary leave of my subject, which, so far from being exhausted, may yet be contemplated under a variety of aspects and conditions. Among these, I may single out in particular the action of bromine on our three acid heterologues, the rationale of which I purpose communicating in one of my next papers.

Finally, and in conclusion, I have deemed it advisable, for the special consideration of those who may desire to prosecute their chemical studies in the spirit of the "typo-nucleus" theory, of appending the following two schemes, for the proper interpretation of which I must refer the reader to the subjoined explanatory note.

Bibasic water-salts :

NOTE.—Let it be understood that the name given to the lowest heterologue of each component group of bibasic or tribasic water-salts is compounded of a prefix, a root, and an affix. The prefix consists of the words *meta* or *ortho*, implying that the molecule is moulded on the formyl type or on the oxalyl type; the root is contained in the name of the parent alcohol; and the affix consists of the syllable *ite*. In the "general guide" this syllable is followed by a given number of affixes, by the substitution of which for the first we are enabled to designate the higher or more oxidised members of each component group. Finally, sets of figures, linked together by twos or threes, and placed below each affix, serve to indicate the relative number of oxygen molecules contained in the acid principal and associated allies of the corresponding bibasic or tribasic water-salts.

ON THE ENERGIES OF THE IMPONDERABLES,
WITH ESPECIAL REFERENCE TO THE
MEASUREMENT AND UTILISATION OF THEM.*

By the Rev. ARTHUR RIGG, M.A.

(Continued from page 93.)

As an illustration of this principle of least action, look at that most extraordinary muscle of all in the animal economy—the heart. Although certain features of its action should come under notice at a later portion of the evening, yet it bears upon the present subject, in that it is a bundle of small muscular fibres. There are probably more than a million of them, complex in their arrangements and perplexingly curious in their relative and combined actions, and yet this, regarded as one muscle, weighs on an average, in man, only 9.39 ozs. Its screw-like construction is such that at each action it propels forward the whole of its contents, leaving no filled-in corners. It has power to propel these contents to the vessels in the extremities of the body. Were not this muscle "up to the mark," these extremities would die for want of nourishment; if, "beyond the mark," then some of the vessels along which the blood is driven might be burst in consequence of a liquid pressure greater than that they were calculated to sustain.

The balances required are perfect, and this little muscle of 9.39 ozs. sends life to all parts of the body—by day and by night—from birth to death. Now the work it is continually performing is as though it lifted its own weight through nearly 20,000 feet in an hour. The height of St. Paul's Cathedral, from the ground to the top of the cross, is 404 feet; therefore the heart could place itself on the top of St. Paul's Cathedral nearly fifty times in one hour. Let a man consider how often in an hour he could ascend, even on the assumption that he was never tired, and then he may obtain an idea how much more work his heart is doing than he can do. Put otherwise, the heart, regarded as we regard a locomotive, can raise itself through a vertical height of nearly 4 miles in one hour. The most powerful locomotives, built specially for the ascent of gradients, can only raise their own weight through about half-a-mile, or one-eighth of that which the heart can do. The directors of an Alpine railway (that from Trieste to Vienna) offered a prize for the locomotive which could lift its own weight through the greatest height in one hour. It was allotted to the locomotive (Bavaria), which lifted its own weight in one hour through 2700 feet, or about half-a-mile. The experiment was simply made by means of inclines or railway lines; the subject this evening does not warrant a larger reference to this matter.

By no contrivance can we make a machine which shall bear such proportions between size and work as the heart does. Here is a little machine, weighing say 10 ozs., put in action and worked by vitality, as a steam-engine is worked by heat; and this little engine, which we could easily put in our pockets, can lift itself 20,000 feet high in an hour. There must indeed have been a master-mind that designed and executed the manufacture of the animal machinery, and so perfectly carried out the "principle of least action."

By careful anatomical and mathematical investigations similar to those which are to be alluded to near the close of this lecture, the daily work of the heart can be shown to be 124 foot-tons. This is nearly one-third of the daily labouring force of the whole body.

This muscle of the heart is not only capable of exerting this wonderful power through the action of the vital force, but it seems not to need any rest, and yet it does not wear out, for the muscles in the heart of an old man are apparently as sound and healthy and fit for continuous

* The Cantor Lectures, delivered before the Society of Arts.

work as those in the heart of a youth. How through life they have been so maintained, how as other muscles in the frame lose somewhat of energetic power, yet these fail not, is one of the many perplexities to science. That muscular power is, as we may say, restored by rest and food, any one who cares to think upon what he experiences and witnesses will readily admit; indeed, further, the nature of the work and the character of the food must be suited each to the other. Now the muscles of the heart never rest. The variation in their energy is within very narrow limits, so narrow that we may say that any series of observations, however long continued and whenever taken—as a series—would always average the same result. Hence the inference that in the animal economy these muscles possess the power (peculiar probably to themselves) of at one and the same time parting with energy and restoring it. This ever-balanced and ever-exerted energy, this actual external utilisation of energy, coupled with a perfectly self-recuperative operation, is what the searcher for perpetual motion, like the asymptote to the hyperbola, is ever approaching, but never attaining.

If men can find out how these particular muscles are exempted from the laws of muscle, with which laws these Cantor Lectures are mainly concerned, they will have advanced further in solving the problem of perpetual motion, which some enthusiast in every generation pursues with commendable, but hitherto unsuccessful, zeal.

The energy of vitality, as utilised and controllable by ourselves, is chiefly through the agency of muscles. The physiologist regards these muscles, with their attached tendons and nerves, as to the functions and offices they discharge in the economy of the individual; we are to regard them as to the external use to which they may be applied, and the work to be obtained from them. How much we copy from Nature may be concluded when we refer to the earliest attempt at locomotion from machinery. It was by basing the form and structure upon the muscles of animals. To thus imitate muscular action has hitherto baffled the ingenuity of man. If anyone has not satisfied himself of the nature of this action, let him put the hand on the muscles of the arm when it is in repose; they are soft and yielding. Let him now make an exertion with the arm, such as raising a weight; the muscles become tense and hard. The weight raised is extraordinary compared with the weight of muscle employed, for it may be from 16,000 to 17,000 times its own weight.

The physiologist considers the striated and unstriated variety of muscle, the nucleated cells, the vitality in each cell, the electrical relations of various tissues. With none of these need we be concerned.

Engineers regard muscles as machines for doing work, and, as it is needful to know the structure of a machine before we can say how it can be made to work, so now the structure of muscle, as a machine, must be considered.

When a muscle is examined after vitality has ceased, it is found to consist of a great number of separate parts, or strings. If this piece of string were a muscle, there would be a bundle of strings or fibres together—just the same as if I had doubled the string several times,—and encasing them there is a covering or sheath, much the same as an india-rubber tube, which covering encloses a number of muscular fibres or strings. That covering has none of the contractile elements of the muscle in it; it is merely an elastic covering enclosing that which has the contractile powers. Then, side by side with this bundle of fibres or strings, in its case, is another one, also covered in the same way, and another, and another. These are kept in their place by the tubing or covering spoken of, and a combination of these is called a muscle, which consists, then, of these fibres, which, again, are separated into fibrillæ. With such a peculiar arrangement of contractile strings, it is clearly a problem for the mathematician and the mechanic to obtain a

solution to the question of how much work can vital energy do when operating through the means of such apparatus as is thus supplied. The muscles are so varied in form, combination, and number, that but little progress has hitherto been made to deduce results and bring them into measurement.

Now, no substance is known that can act the part of a muscle. A muscle left free is in the state of an india-rubber band when slightly stretched. It is called into action by contracting—exactly the converse to that of india-rubber, which is brought into action by being stretched. A number of these fibres are put together, and form a group like a number of india-rubber bands. Sometimes the groups act in a straight direction, sometimes they take a sloping form. If they take a straight form, and if we know the number of fibres and the power of endurance of one, it is easy to calculate the power of the whole; but, if the muscle acts diagonally, then it brings in the parallelogram of forces, and we need the mathematician to deduce the amount of energy which can be utilised by this form. Sometimes the fibres are twisted like a screw, sometimes they spring from one point and spread out like a fan, and all these screws and fans the mathematician must get hold of and calculate; this is now being done.

Having endeavoured very briefly to explain the mode in which animal vitality can be utilised through the agency of muscle, it may perhaps be well to state that between that part of the system where the will is localised and the muscle, there are telegraphic ramifications of nerves. These nervous processes enter within the muscle, and, by some means unknown to us, influence the muscle to exert its mechanical powers—convey, in fact, the will to that agent which is expected to do its bidding through the power introduced by vitality.

With this nerve power we are not concerned. The nerve as a material substance is intermediate between the will and the muscle; it has nothing to do with the amount of work done; its business is chiefly to connect the mental and the material processes of life. Of that which is the will, of that which travels along the nerve in consequence of the will, we know nothing. Call it electricity; that is not any advance, for we know nothing of what electricity is. The first region in which the vital power gives a measurable evidence is when the muscle begins to act. Prior to that all is speculation, and furnishes a very pleasant hunting-ground for physiological enthusiasts.

Whether muscle is a means or apparatus for the transformation of force, or whether it is the material out of whose chemical changes or electrical states force and consequent energy result, are beyond our present knowledge. A plant transforms light into energy; so may muscle transform what, for want of a better name, may be called vitality into energy, and yet not be itself consumed or destroyed. Although, for obvious reasons, that energy which is localised in animals is called the energy of vitality, yet it must not be inferred that such energy or source of energy is self-existent. The animal extracts it in those wonder-working laboratories, the stomach and the lungs. By some unknown process it is deposited in the muscle as potential energy, and awaits the decision of the will as to when and how it shall become kinetic. Although ignorant of the analytical chemistry of vitality, yet we are not ignorant of the materials with which it experimentalises. With this knowledge we must rest; we cannot repeat the experiments vitality makes. Given every material and contrivance within reach, neither the physicist nor chemist, separately or jointly, can accomplish the phenomena with which the changes of these ingredients are concerned when they are associated with the vital principle.

To form an estimate of the number of the fibres in any muscle is an investigation requiring more of care and caution than of difficulty. Determining from a series of averages the magnitude of one—i.e., the area of cross section of one muscular fibre,—and knowing the area of

the section of muscle, the number is merely the quotient of the division.

The muscles are exceedingly small and delicate, and the way their size is calculated is by cutting a piece of cardboard exactly to the section of the muscle. Then another piece is cut out of the same cardboard to, say, a square form, and they are weighed against each other until the square card is exactly the weight of the irregular piece. Thus, when the weights are equal, the areas are equal, and, by calculating the area of the square piece, you are able to arrive at the area of the section of the irregular muscle. By the aid of a powerful microscope, we can ascertain the size of a section of one of these fibrillæ, and it is found to be in men $\frac{1}{100}$ th of an inch in diameter, so that in an inch there would be 350 of them; in women it is about $\frac{1}{120}$ th, i.e., in 1 inch there would be 450 of them. It may here be mentioned that these elementary fibres are not circular, but polygonal, owing to their mutual pressure, and at the angles of the polygons are the vessels which supply blood. Hence it obviously follows that where these fibrillæ are very small, the supply of the blood, which is the food of the muscle, can get at them more readily than when they are very large. Where they are large they have greater strength, that is, can lift heavier weights, but where they are small they will have greater endurance, because more freely and easily supplied with blood. Hence, as they are smaller in women than in men, the muscles of women have more power of endurance, but not the same strength as those of men. If a man wishes to test this, he has only to nurse a child, and then compare the length of time he could do so without fatigue with the length of time for which a mother can nurse it, and he will soon find the difference, and give a verdict adverse to himself.

There are two muscles in the arm, with which we are especially concerned in estimating the measurement of such vital energies as we may utilise; indeed, it may suffice to consider that the muscles in the arms and legs are the only ones to which the subject of this evening's lecture directs attention, and we may illustrate the question of the great number of muscular fibres by calculating, in the mode described their presence in the two most important muscles in the arm—viz., the one called "biceps," the other called "brachialis anticus." In the biceps there were found to be 449,000 elementary fibres; in the brachialis there were found to be 349,000; total, in these two muscles of the arm, 798,000 fibres.

(To be continued.)

NOTICES OF BOOKS.

Programm der Königl. Rheinisch-Westphälischen Polytechnischen Schule zu Aachen für den Coursus 1873-74.

Announcement of the Stevens Institute of Technology, a School of Mechanical Engineering founded by Edward A. Stevens. Hoboken, N.J., U.S.A. 1873.

WE owe to the courtesy of the directors of the establishments just alluded to the opportunity of calling attention to two excellent schools established, the one by the care of the Prussian Government, the other by the munificence of a late eminent citizen of the great Transatlantic Republic.

In the Programme of the Polytechnic School at Aachen (Aix-la-Chapelle) we meet with a very clear and succinct review of polytechnic science in all its bearings and applications, as taught by a staff of some forty teachers, while the headings of the various subjects in which instruction is given amount to about one hundred. The school is now attended by about four hundred pupils, many of whom are natives of non-German countries.

Although an institution due to private munificence, the Stevens Institute of Technology can worthily vie with the now already celebrated School at Aachen. The Stevens

Institute is just as much a high polytechnic school as the German one, and to the eminent President of the American school, Dr. H. Morton, high credit is due for the manner in which he has assisted the trustees of this foundation to carry out the will of the late Mr. E. A. Stevens.

Our space does not permit us to enter into a detailed review of the two volumes, the titles of which are recorded above. Both books have a permanent value, and the American contains, aided by woodcuts, a description of some of the most prominent portions of the contents of the museums and collections of apparatus for illustrating lectures on physical, chemical, and engineering sciences. While calling attention to these institutions, we cannot but express our great regret that in this country nothing exists which even approaches either of the two establishments of which the programmes have been courteously sent to us.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Under this heading will be found an encyclopedic list of chemical papers published abroad during the past week, with abstracts of all susceptible of advantageous abridgment. The two half-yearly volumes of the CHEMICAL NEWS, with their copious indices, will, therefore, be equivalent to an English edition of the "Jahresberichte."

NOTE. All degrees of temperature are Centigrade, unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances de l'Académie des Sciences, August 4, 1873.

Reciprocal Displacements among the Hydracids.—M. Berthelot.—It is known that the reciprocal displacements among the hydracids are generally the reverse of those which take place among the corresponding elementary bodies. Chlorine expels bromine from bromides, which in turn drives out iodine from iodides, whether soluble or insoluble. But hydrobromic acid decomposes chloride of silver and alkaline chlorides, and hydriodic acid decomposed both the chlorides and bromides of silver, and of the alkaline metals. There is a similar contrast with oxygen and sulphur. This reversion of phenomena the author explains by the reversion of the thermic sign of the reactions. He has examined, both from a chemical and thermic point of view, the reactions of hydrochloric, hydrobromic, hydriodic, hydrocyanic, and hydrosulphuric acids upon oxides, and upon alkaline and metallic salts, as well as their reciprocal displacements. He finds that the thermic action of the three halogens gives place to reactions more closely alike to each other in case of silver than of potassium. The resemblance is still closer with mercury. It cannot be admitted that the mutual substitution of halogens gives rise in general to thermic effects which are constant, or even multiples of one common constant. On the contrary, such an approximate constancy exists with the salts of the alkaline metals, and with the acid chlorides, bromides, and iodides derived from certain non-metallic elements or organic compounds.

Polychromic Photography.—L. Vidal.—The process by which the author has obtained polychromic images is an extension of the "carbon process," described in his application for a brevet, December 23, 1872. For stearine paper he has substituted a vegetable paper coated with gum-lac. Polychromic proofs may be obtained either by optical means more or less precise, and analogous to those described by Ducos du Hauron, or by reserving on each of a series of monochromic proofs all the parts which ought to contribute, by a greater or less degree of transparency, to the formation of the monochrome. In copying nature, if it is desired to produce the red monochrome,

everything is covered with an opaque resist, such as vermilion or lamp-black, which contains neither red nor combinations of red with other colours. A similar process is repeated with blue and other colours. Each of the proofs concurring in the formation of a polychromic plate is then printed on a mixture of the desired colour, and developed on a provisory support.

Analysis of Dewalquite from Salm Chateau in Belgium.—F. Pisani.—This mineral has been known also under the names of ardennite and mangandiethen. Its composition is—

Silica	28.40
Alumina	24.80
Ferric oxide	1.31
Manganic oxide	25.70
Lime	2.98
Magnesia	4.07
Oxide of copper	0.22
Arsenic acid	6.35
Vanadic acid	3.12
Water, and loss on heating	5.20

102.15

On Nitrification.—Th. Schloesing.—(Continuation.)—If there is no oxygen in the atmospheric air confined in the soil it becomes a reducing medium, and the nitrates are doubtless destroyed, though the nature of their products of decomposition is not known. Kuhlmann has proved that nitric may be converted directly into ammonia. On the other hand, liquids of organic origin—such as the juices of beet-root, tobacco, or urine—yield a variable mixture of protoxide and binoxide of nitrogen, and free nitrogen. The decomposition products of the nitrates are therefore not constant, and depend on the nature of the surrounding medium. The mode of the decomposition of the nitrates, when the medium is a soil deprived of oxygen, has not been examined, and is a very interesting question. Earth of known composition mixed with known amounts of nitrates, and kept from November 20, 1872, till January 24, 1873, at temperatures ranging from 14° to 22°, showed that the reduction of the nitrates had not yielded 1-15th of the ammonia which would have been its equivalent; on the contrary, there is disengagement of free nitrogen. In another experiment earth kept in an atmosphere free from oxygen lost as much nitrogen as was originally present in the form of nitrate, and even more. Boussingault has shown that in a confined oxygenated atmosphere gaseous nitrogen does not contribute to the formation of nitric acid in soils; but that these, on the contrary, lost a portion of their combined nitrogen. The author finds the same result in an atmosphere void of oxygen.

Corundum of North Carolina, Georgia, and Montana.—Lawrence Smith.—In North Carolina corundum is found in rocks of chrysolite or serpentine, lying parallel to and on the north-west side of the main mass of the Blue Mountains. On the beds of serpentine are found chalcodony, chromite occasionally, chlorite, talc, steatite, anthophyllite, tourmaline, emeryllite, epidote, zoisite, albite, asbestos, picrolite, actinolite, and tremolite.

Essence of Roman Chamomile.—E. Demarçay.—The author finds that this essence is a mixture of several ethers, among which the angelates and valerianates of butyl and amyl predominate.

Characteristics of the Polyatomic Alcohols, properly so-called.—M. Lorin.—The author considers that the property of producing oxamide may serve to recognise and define the chemical function of an alcohol, whatever may be its atomicity. The polyatomic alcohols, properly so-called, decompose above 100° common oxalic acid into water, carbonic acid, and formic acid. They combine successively with a part of the formic acid; and yield finally, on the one hand, a formine of the alcohol employed, and on the other, aqueous formic acid.

Variations in the Excretion of Urea under Normal Diet, and under the Influence of Tea and Coffee.—E.

Roux.—The author finds that in his case, at least, coffee and tea do not hinder the wear and tear of the tissues. Their effect seems, however, to diminish the longer they are used.

M. Vicaire's Physical Theory of the Sun.—M. Faye.—M. Vicaire's theory is, briefly, as follows:—The sun is a combustible mass burning (since a certain epoch) in an immense atmosphere of oxygen; which must extend beyond Mars' orbit, the tails of comets being produced by it. The central mass consists of metals chiefly, with hydrogen and carbon in combinations permitted by a comparatively low and constant temperature. It is liquid (at the surface at least), and gives off vapours which burn in the oxygen, producing the photospheric mass of flame with a temperature much higher than the interior. This temperature keeps constant in the same way as that of a candle flame. The products of combustion are partly gaseous (water, carbonic acid, &c.), partly solid (silica, earths, metallic oxides). The latter along with carbon, where oxygen is not in excess, produce the bright light of the photosphere. The oxidated matters floating at the surface of the photosphere unite in large scoriaceous masses, and fall into the interior liquid sea, producing the various phenomena of faculæ, spots, and protuberances. M. Vicaire supposes our earth—primitively formed of combustible matter, and surrounded with pure oxygen—to have taken fire and burnt some time. The arrest of the combustion would leave such products as we find. This hypothesis he transfers to the sun. In his criticism M. Faye, citing Laplace's hypothesis, thinks it impossible that in the period of cooling the chemical actions should have been completely suspended; so that there should be this absolute separation between metals so readily oxidised (even in cold), and a vast reservoir of free oxygen. Further, the enormous extent of the oxygen atmosphere is a difficulty. Laplace held the sun's atmosphere could not reach the orbit of Mercury (as the outer layer could not extend beyond where centrifugal force balanced gravity). If the products of combustion become gaseous, and are diffused throughout an atmosphere more than 110,000,000 of leagues diameter, the sun ought to become a source of cold. If, on the other hand, the products are solid, the constant passage of oxygen towards the nucleus must generate heat; but then there must also be an angular acceleration of the envelope producing this, and not a retardation, as is supposed. There remain physical and mechanical difficulties connected with the presence of four planets, &c., within the huge atmosphere. The intensity and duration of solar radiation are against the hypothesis; the heat would not last with constant intensity longer than historic times. The candle comparison is not exact; for in the sun it is supposed that the solid products of combustion fall incessantly on the surface of supply, while the gaseous products progressively vitiate the atmosphere. A sun so constituted would soon be encrusted and extinguished, instead of lighting and heating our earth during immense periods. Then it is difficult to conceive how the pulverulent and light oxides, arising from combustion of calcium, magnesium, &c., agglomerate in those huge blocks; remaining suspended till they acquire sufficient density and volume to produce by their fall spots, faculæ, &c.; and how do such incandescent masses produce indifferently dark spots and bright faculæ? These scorizæ, moreover, are not supposed to be thin pellicles, but enormous rigid masses capable of resisting for entire months the ebullition of the metallic ocean, and of intercepting the vapours which seek exit by their edges, and thus, M. Vicaire thinks, produce penumbrae. M. Faye thinks the vertical section of a spot is entirely against this idea. He concludes with a *résumé* of eight different theories of the sun's constitution.

Determining the Wave Lengths in the Infra Red Part of the Spectrum by means of the Effects of Phosphorescence.—M. E. Becquerel.—M. Fizeau has shown that if a thin plate (mica, &c.) be put before a slit

admitting solar rays from a heliostat into a dark room, there appear interference bands in the spectral image. Their number between certain limits is related to the wave lengths of the corresponding rays. They are very indistinct, however, the direct and twice-reflected rays having different intensities. M. Becquerel substitutes for the metallic plate of the heliostat a thin plate of mica on a plane non-reflecting surface. The rays reflected from the two surfaces of this plate have comparable intensities, and the bands are alternately bright and dark. One such plate, having a thickness less than $\frac{1}{10}$ of a millimetre, gave 11½ fringes between the lines B and D of the solar spectrum. A somewhat thicker plate gave 35; but for phenomena of phosphorescence the number should be less, and the mica not more than $\frac{1}{100}$ m.m. thick. The phosphorescent substances, pulverised, are submitted to the spectrum thus crossed by interference bands. In the ultra violet the parts unequally active are distinctly shown; in the infra red they are less distinguishable, and very thin mica plates should here be used, as also a brightly phosphorescent substance like hexagonal blende. M. Becquerel finds wave lengths in some parts of the infra red exceed the double of the extreme red. But he does not yet furnish details.

Use of Armatures applied to Magnetic Bundles.—M. Jamin.—If several magnetised plates are superposed they react on each other, each destroying, in part, the magnetism of its neighbour; so that the portative force of the bundle is less than the sum of the forces of the plates considered separately. M. Jamin has found a means of preventing reaction and weakening for a time. He magnetises each plate separately; applies to it a well-fitting contact of the same thickness, which neutralises it; then superposes plates and contacts, fixing with screws the magnets together and the contacts together. This does not destroy the neutrality of the elements, but hinders their reaction. Thus to detach all the contacts a weight of 115 kilograms was necessary, or a little above the sum (108) of the individual forces. Immediately the contacts are detached the plates cease to be neutralised; their magnetism reappears; they react on and weaken each other as before. Superposed plates with an armature are less charged (magnetically), and so react less on each other. Armatures weaken the magnetic intensity; their part is to offer a space where magnetism may collect and be preserved, which would otherwise be destroyed in consequence of mutual reaction between the constituents of the bundle.

Cubic Space and Volume of Air necessary to Ensure Healthiness in Inhabited Places.—Gen. Morin.—The author gives a formula indicating what amount of air should be renewed hourly for each individual, in order that carbonic acid and vapours exhaled may not accumulate beyond a proportion of 0.0008 in a given enclosed space. He finds that in a cubic space of 10 cubic metres this renewal hourly should be 90 cubic metres; in 12, 88; in 16, 84; in 20, 80; in 30, 70; in 40, 60; in 50, 60; in 60, 40. Various applications of the formula are suggested—barracks, bedrooms, public halls, hospitals, &c.

Direct Demonstration of the Fundamental Principles of Thermo-Dynamics.—Continued extract from memoir by M. Ledieu.—The author here treats of the calorific energy and equilibrium of bodies; and gives a demonstration of the principle of mechanical equivalent of heat.

Memoir on Cerebral Localisations, and on the Functions of the Brain.—Dr. Fournié.

Maximum Resistance of Magnetic Coils.—Fourth note by M. du Moncel.—The author has shown in these notes—(1) That a given helix produces its maximum effect when its proper resistance is greater than that of

the exterior circuit in the proportion of 1 to $1 + \frac{c}{a}$; (2) that

with the same diameter of coil the helix giving the best results is that in which the wire has such thickness and

length that its resistance represents that of the exterior circuit; (3) that the thickness of magnetic helices should be equal to the diameter of the magnetic cores they surround; (4) that their length should be equal to this diameter multiplied by 11, or, practically, by 12.

Electrical Condensation.—Extract from memoir by M. Neyreneuf.—The air surrounding an electrified body experiences, like all insulating bodies, the effect of penetration in the nearest molecules, and of orientation in the more remote. The former act, in the production of a spark, not by direct transmission, but like the insulating plate of a condenser, i.e., by decomposition, by induction.

Uniformity of the Heart's Work when this Organ is not Subject to Exterior Nervous Influence.—M. Marey.—The author removes the heart of a tortoise, and adapts to it a system of fine caoutchouc tubes, representing arteries and veins. On contracting the artificial artery, and so increasing the resistance, the heart's movements are retarded; on lessening the resistance the beats are accelerated.

Effects Produced by Lightning at Troyes, on July 26, 1873.—M. Parent.—One interesting feature is the appearance of several balls of fire. One falling before a young woman rolled along the street, then disappeared; while hair pins, and other pieces of metal about her person, were violently torn out. Other incandescent bodies were afterwards found in a cooled state; one was like a piece of calcined stone, but was surprisingly light; some parts of it were dirty grey with black points, others reddish with bright reflection. The lightning produced some curious effects on a public building in the place.

Bulletin de la Societe Chimique de Paris, tome xx., No. 3, August 5, 1873.

In the session of July 4 M. Prud'homme communicated some facts relating to rosolic acid. When phenol is heated with sublimed oxalic acid to 110° to 120° there is obtained a body which dissolves in water, and deposits in the form of a red powder. The solution dyes wool and silk like rosolic acid. The alkalies turn it to a rose colour. On heating to 180° we obtain rosolic acid, which precipitates in water as a green powder. The red powder and the rosolic acid yield with hydrosulphite of soda colourless compounds, soluble in water and alcohol. The combination which rosolic acid yields should be identical with that which Dale and Schorlemmer have obtained with the bisulphites. Schützenberger has shown the identity of the compounds formed by the hydrosulphite and the bisulphites with the hydride of benzol.

On Tereben.—M. J. Riban.—The author describes the preparation of tereben; its properties, its transformation into polymers, and into cymen, and the production of a camphoric matter.

Heat of Combustion of Formic Acid.—M. Berthelot.—This paper treats also of the heat of combustion of oxalic acid; of the heat developed by the reduction of permanganate of potassa, and of the oxidation of formic acid. It may be regarded as a continuation of the Berthelot-Thomsen controversy.

Researches on Chlorine and its Compounds.—M. Berthelot.—Another thermo-chemical controversial paper. The author examines the action of chlorine upon water, upon the mercurous and stannous chlorides, and ferrous sulphate.

Compound of Picric Acid and Anhydrous Acetic Acid.—D. Tommasi and H. David.—By the mutual reaction of these two bodies a compound is obtained of the formula—

which may be regarded as a picrate in which the atom of metal is replaced by acetyl.

Glycerin of the Aromatic Series.—Ed. Grimaux.—The substances examined are—dibromhydric styrcerin; aceto-dibromhydric styrcerin; tribromhydric styrcerin; hydrochloric-dibromhydric styrcerin; triacetic styrcerin; and pheno-glycerin.

Process for the Quantitative Determination of Aniline Colours by Means of Hydrosulphite of Soda.—A. Stamm.—Up to the present time there has been but one process for determining the value of a colouring matter. It consists in dyeing or printing with the different samples, and comparing the intensity of the shades produced. This method answers perfectly for industrial purposes. But there exists no chemical procedure for determining these bodies, and proving their purity. The author considers that he has effected this object with simplicity and precision, by making use of the power which hydrosulphite of soda possesses of reducing and decolourising different tinctorial bodies, and, amongst others, those derived from aniline. The apparatus employed is essentially the same as that which Schützenberger and Risler employ for the determination of oxygen dissolved in water. The hydrosulphite is drawn up by aspiration into a Mohr's burette. The solution to be titrated is poured into a small flask closed with a caoutchouc stopper, pierced with three holes. Through one of these passes the delivery-tube of the burette, whilst the other two serve for admitting into the flask a current of carbonic acid gas, since the experiments must be made in the absence of atmospheric air. Lastly, as the decolouration of these matters only takes place at 100°—except in case of magenta which is decolourised in the cold—the flask is placed on a sand-bath, and the contents kept at the boiling-point. If it is required, *e.g.*, to analyse a sample of magenta, we weigh out 1 to 2 decigrammes, which are dissolved in water and diluted to a litre. At the same time a solution is prepared of 1 or 2 decigrms. of pure magenta in a litre of water. All that is required is to determine how many degrees of the hydrosulphite are required to decolourise each of these solutions. The ratio of the two numbers gives the value of the solution under examination. Other colouring matters have been titrated, and on comparing the results obtained it is found that 1 molecule of each of these different bodies whose composition is known requires for its decolouration the same quantity of hydrosulphite as would be consumed in reducing 2 molecules of ammoniacal sulphate of copper. This method offers another advantage—it enables us to judge of the quantity of colouring matter contained in an unknown liquid. It may be also used during the manufacture of aniline blues and violets to ascertain the amount of colouring matter which has been formed.

Compounds of Chloride of Titanium with the Ethers.—Eugène Demarçay.—The chloride of titanium is capable of combining with the oxygenated ethers, and with the alcoholic sulphides and hydrosulphites. With acetic ether it forms three compounds, as also with benzoic ether, with the butyrate, valerate, caproate, and angelate of ethyl, the valerate and acetate of amyl, and the benzoate of methyl. The ethers formed by bibasic acids furnish analogous compounds, but less stable. Oxalic and succinic ethers give two compounds. In constitution these compounds may be considered as chlorhydrines analogous to the silicic chlorhydrines of M. Friedel, united to the chlorides of acid radicals.

Manufacture of Gelatin.—M. F. Heuze.—The author's object is to obtain white gelatin from products of low quality. He attempted first to bleach the brown or nearly black gelatin, which is obtained as a secondary product in the manufacture of neat's-foot oil. This gelatin is applicable to very few uses on account of its dark colour, and is sold at 42 francs per 100 kilos. To prepare it, the feet—after removal of all parts useful for the turners—are digested in water or superheated steam at a pressure of 3 atmospheres. After three hours of digestion, and half-an-hour for settling, the strongly

ammoniacal solution of gelatin is concentrated; the supernatant oil having been previously removed. A dark brittle gelatin is thus obtained. The author tried to bleach it with sulphurous acid, or with a sulphate in presence of hydrochloric acid, but the results were unsatisfactory. He attempted then to modify the process of manufacture itself, diminishing the duration of the action of the superheated steam. Instead of drawing off all the liquor at the expiration of three hours, it was drawn off three times from hour to hour. The solution was then mixed with wood charcoal mixed with 25 per cent of animal charcoal, and after standing twelve hours was treated as above. The solution requires 4 per cent of the charcoal mixture. The product is a gelatin of good quality, which only presents a yellow tint when seen in large masses. It is tasteless and scentless, and is even fit for alimentary purposes.

Waterproof Glue.—Bichromate of potassa has the property of rendering insoluble, under the influence of light, certain organic bodies, such as gum, glue, glycerin, &c. If a paper covered with gum mixed with bichromate is exposed to light, the coating becomes quite insoluble even in boiling water. This property is utilised in the so-called "carbon" photographic process. Strong glue becomes insoluble more rapidly than gum, and the action takes place slowly even in the dark. A concentrated solution of bichromate is prepared which is kept in the dark, and a little of which is added to boiled gelatin. Objects glued with this, after some time can be washed either with cold or hot water.

Preparation of Parchment Paper.—M. J. Stinde.—The paper is prepared with the chromatised gelatin mentioned above. It serves in the preparation of the peasauses used in the German Army.

Improvements in Photo-Lithography.—M. Paul.—The paper is coated with a layer of white of egg beaten up and mixed with a concentrated solution of bichromate. When dry it leaves a hard smooth surface. After a sufficient insolation under the negative, the paper is covered with lithographic ink, then immersed in cold water to dissolve out the unchanged albumen, which is then removed with a fine sponge.

Bulletin de la Societe Francaise de Photographie.
No. 7, 1873.

M. Despaquis presented to the Society proofs in Judea bitumen, mounted between two cards with an opening, and visible either by transmitted or reflected light. These proofs are stable, of a low price, fine in details, and have a pleasing sepia tone.

M. Briois, on behalf of M. de Sars, submitted to the Society a simple instrument, by means of which dried plates may be changed in full daylight.

Preparation of Albumen Plates by a Modification of Gaumé's Process.—M. Clouzard.—The author employs the following collodion:—

Ether		50 c.c.
Alcohol at 36°		50 c.c.
Soluble cotton		0.70 grm.

To prepare the albumen the author dissolves in 40 c.c. of water:—

Gum arabic in powder		2.5 grms.
Milk-sugar		1.0 "
Iodide of ammonium		3.0 "
Bromide of ammonium		1.0 "

This solution is added to 100 c.c. of albumen dissolved in acetic acid according to M. Acloud's directions, and the whole is carefully filtered before use. The plates being prepared with the collodion and albumen, and well dried before being rendered sensitive, are submitted to the vapour of iodine for thirty seconds, when the temperature is from 18° to 20°.

Silver Bath.

Water	90 c.c.
Acetic acid	12 c.c.
Nitric acid	4 c.c.
Nitrate of silver	10 grms.
Iodide of ammonium	0.10 grm.

The precipitate of iodide of silver formed is left for some time in the solution, and stirred in order to saturate the liquid as much as possible. To render the plates sensitive they are immersed in this bath for a minute and a-half if the temperature is 18° to 20°.

Developing Bath.

Water	100 c.c.
Liquid ammonia	1 c.c.
Alcohol	2 c.c.

Water	100 c.c.
Bromide of potassium	0.25 grm.

1 volume of the second solution is mixed with 3 of the former; and this mixture is poured upon the plate previously moistened. The liquid is re-collected in a glass, and pyrogallic acid is added in the proportion of 0.5 grm. to 100 of the liquid employed. When the pyrogallic acid is dissolved the solution is again poured upon the plate, when the image appears in full detail if the exposure has been sufficient.

Application of Aniline in Photography.—M. Trouquoy.—This process has been previously noticed.

New Method of Removing Hyposulphite of Soda from Proofs on Paper.—M. Hermann Gunther.—The quantity of water needful for washing the proof may be diminished, and a better result obtained by using a solution of eau de javelle (hypochlorite of soda). In practice the proofs, after fixing, are washed in three successive baths of pure water. They are then passed into water containing a few c.c. of eau de javelle, and finally washed in pure water.

Suppression of Gold in Toning.—M. Bodgers.—The author prepares his silver bath at 6 per cent, and adds 10 drops of ammonia, and 10 of a saturated solution of alum per litre. On this bath the paper is floated three to five minutes according to the temperature. The impression is feebler than if chloride of gold had been employed. After exposure the proofs are washed for fifteen to twenty minutes, and then plunged in the following bath. Into $\frac{1}{2}$ litre of water press the juice of five lemons, add 15 grms. acetate of soda, and 7.5 grms. of powdered alum, dissolve and filter. Pour 15 to 30 grms. of this solution into 2 to 4 litres of water; plunge the proofs into this bath, and let them remain five to ten minutes. Then submit them to the ordinary toning bath, substituting for the gold alum water in the proportion of 20 drops per litre of water. Let them remain two or three minutes only. Wash again, and fix with hyposulphite mixed also with alum (15 drops per litre of water).

Les Mondes, Revue Hebdomadaire des Sciences, par L'Abbé Moigno, Tome xxxi., No. 15, August 7, 1873.

Artificial Sugar.—The *Assemblée Nationale* promulgates a rumour that M. Jouglot has succeeded in forming sugar artificially, and at the low price of 5 francs per 100 kilos.

No. 16, August 14, 1873.

Prevention of Epidemics.—M. Chodzko.—The author declares that the phenols, the hypochlorites, and chlorine merely mask deleterious emanations without destroying them. He professes to have discovered a means of disinfection which neutralises all putrid effluvia. The process can be executed with rapidity, and costs only 10 centimes per cubic metre. (Unfortunately no indication is given as to the nature of this new disinfectant.)

Action of Iodine upon Caoutchouc.—M. Baumetz.—India-rubber tubes, whether vulcanised or not, if sub-

mitted to the action of iodine increase rapidly in bulk, and grow hard and brittle.

Double Phenomenon of Incandescence by Oxidation and Reduction.—M. Thomsen.—A cylinder is made of oxide of copper and gum-water. When dry it is reduced at a low temperature in a current of hydrogen. If while still hot this cylinder of reduced copper is placed in an atmosphere of oxygen it becomes immediately incandescent, and remains so till the oxidation is complete. If while still hot it is transferred to an atmosphere of hydrogen, a new incandescence takes place, due to the reductive action of the hydrogen.

Agricultural Value of the Human and Animal Excrement Annually Produced in France.—Taking into account merely nitrogen, phosphoric acid, and potash we find the following values:—

	Head.	Frs. c.	Francia.
Human	36,000,000 at 15.13	=	544,680,000
Oxen, &c.	10,000,000 at 181.94	=	1,819,400,000
Horses	2,000,000 at 132.74	=	398,200,000
Sheep	35,000,000 at 15.38	=	538,300,000
Swine	6,000,000 at 23.55	=	141,300,000

3,441,900,000

The total amount of nitrogen contained in the excrements is 1,141,950,000 kilos.; which, at 40 kilos. per hectare annually, would manure all the cultivated lands in France, amounting to 27,476,000 hectares.

Polytechnisches Journal von Dr. E. M. Dingler, No. 5, 1873.

Investigations on the Solution of Gases in Cast-Iron, Steel, and Wrought-Iron.—L. Troost and P. Hautefeuille.

Recovery of the Gold which is Carried off along with Chloride of Silver during the Process of Refining with Chlorine.—Ad. Leibius.

Coal-Tar and Pitch.—E. A. Behrens.

Determination of Alcohol in Fusel Oil.—G. L. Ulex.

Respiration and the Internal Air of Beet-root.—A. Heintz.

A Fruitful Source of Ammoniacal Salts.—Bruno Terme.

Removal of the Refuse of Towns.

MISCELLANEOUS.

The Adulteration Act.—Mr. Wanklyn has been appointed Public Analyst to the County of Buckingham.

Photographer to the Shah.—We learn that Mr. A. J. Melhuish, F.R.A.S., has received the honour of special appointment as Photographer to His Imperial Highness the Shah of Persia, the reason assigned by the Shah for conferring this honour being that he had never had portraits which pleased him so much, although he had sat to artists at St. Petersburg, Berlin, and Paris.

PATENTS.

ABRIDGMENTS OF PROVISIONAL AND COMPLETE SPECIFICATIONS.

Improvements in the manufacture of artificial manure. Edward Charles Hamilton, Colchester, William Richard Preston, Harold Court, Romford, and Henry Jones, Colchester. January 16, 1873.—No. 187. According to this provisional specification, sewage is mixed with or filtered through waste wool, wool dust, or shoddy; the materials are brought to a pulverulent form.

Improvements in the manufacture of gas. Miles Williams, Lion Oil-Works, Wigan. January 17, 1873.—No. 205. This invention consists in forcing steam and oleaginous substances, more particularly hydrocarbon oils together, through an ordinary red-hot fireclay or iron retort filled or partially filled with coke, charcoal, or other similar substances. The gas so generated may be used, either alone or mixed with ordinary common coal or canal-gas generated in the usual manner the result being a better and more economically produced gas.

An improved process of gilding on glass. Valentin Schwarzenbach, Professor of Chemistry at the University of Berne, Switzerland. January 18, 1873.—No. 208. Take a solution of pure gold, that is to say, free from all other metals, effected by the ordinary chemical process. When pure gold is employed, the work is simple, since it is merely necessary to melt it in aqua regia or nitro-muriatic acid, and to evaporate it in the bain marie till it crystallises; in all other cases the operation is more complicated, on account of the manipulations necessary for separating the other metals, and it is generally requisite to precipitate the gold once by oxalic acid or by sulphate of iron, to bring it to the desired state of purity. In all cases the crystallised mass of perchlorate of gold should be brought to boiling-point with the water destined for its solution, as it invariably contains a considerable quantity of chloride of gold insoluble in water, which slowly decomposes in a cold state, very gently in perchlorate or in metal, but which is instantly effected by coction. After filtration, the solution of gold is ready for use; its dephlegmation is regulated so that 200 c.c. contain 1 grain of metallic gold. This solution is then rendered alkaline by soda lye of mean strength, that is to say, a sufficient quantity is added to it to turn red litmus-paper blue; the addition of the soda should not cause any precipitate, and should never trouble the auriferous liquor; the quantity of soda must necessarily vary according to the dephlegmation of the solution. Before mixing the gold solution with the principal reactive destined to the reduction of the metal, it is indispensable to prepare the surface of the glass to be gilt with the greatest care, employing the same manipulations and materials used for cleaning photographic glasses; the reactive reductive is then prepared by saturating 30 per cent of spirits of wine with a current or mixture of marsh-gas or olefant-gas; this operation completed, the spirits of wine is freed with its volume of distilled water. The glass to be gilt is then disposed horizontally on another surface of glass, separated from it about the space of 3 m.m.; then 25 c.c. of alcohol saturated with the gases is mixed with the auriferous solution; the liquid is then poured between the two glasses, and then left to stand for 2 or 3 hours, at the expiration of which time the gilding is completed. The upper gilt plate is then removed, carefully washed, and varnished.

Improvements in the manufacture of meat extract. Thomas Frederick Henley, St. George's Square, Pimlico. January 18, 1873.—No. 212. The object of this invention is so to treat meat for obtaining meat extract as to utilise all the elements of its composition instead of (as in the Liebig process) utilising only the soluble salts thereof.

NOTES AND QUERIES.

Pure Anthracen.—I should be glad if your readers would inform me of the best way of preparing crude commercial (say 30 per cent) anthracen, and also give me a good plan for the quantitative estimation of the same.—A. M. G.

"Charqui" and "Dampier."—Permit me to call your attention as Editor to *CHEMICAL NEWS*, vol. xxviii., p. 65. "Charqui, or dried beef, the damper of the Australian squatter." This requires explanation, the word "damper" in Australia being applied to a cake of flour and water.—E. DOLBY.

French Imperial Green and Persian or Chinese Red.—I should feel greatly obliged if some of your readers would sketch briefly the cheapest commercial processes employed for the production of the following pigments:—(1). *French imperial green*, which appears to be a mixture of chrome yellow and Prussian blue, but which far surpasses in beauty all the ordinary chrome greens. (2). *Persian red*, sometimes called *Chinese red*.—This seems to be a dichromate of lead; but the original process of Liebig and Wöhler has, I believe, been superseded by much less expensive modes of manufacture. I have tried two processes mentioned in "Wagner's Technology" (English Edition, p. 66), viz., treatment of chrome yellow with caustic potassa solution, and Professor Dulong's process, but (perhaps through some fault of manipulation) I have failed to obtain a more brilliant colour than chrome orange.—I. HOWARD HUNTER.

British Association for the Advancement of SCIENCE
22, Albemarle Street, London, W.

The NEXT ANNUAL GENERAL MEETING will be held at BRADFORD, commencing on WEDNESDAY, September 17.

President Designate:

Professor A. W. WILLIAMSON, Ph.D., F.R.S., F.C.S.,

In the place of J. P. JOULE, D.C.L., LL.D., F.R.S., who has resigned the Presidency in consequence of ill health.

NOTICE to CONTRIBUTORS of MEMOIRS.—Authors are reminded that, under an arrangement dating from 1871, the acceptance of Memoirs, and the days on which they are to be read, are now, as far as possible, determined by Organising Committees for the several Sections before the beginning of the Meeting. It has therefore become necessary, in order to give an opportunity to the Committees of doing justice to the several communications, that each Author should prepare an Abstract of his Memoir, of a length suitable for insertion in the published Transactions of the Association, and that he should send it, together with the original Memoir, by book-post, on or before September 1, addressed thus—"General Secretaries, British Association, 22, Albemarle Street, London, W. For Section..." If it should be inconvenient to the Author that his Paper should be read on any particular day, he is requested to send information thereof to the Secretaries in a separate note.

G. GRIFFITH, M.A., Assistant General Secretary, Harrow.

The OWENS COLLEGE, MANCHESTER.

Principal—J. G. GREENWOOD, B.A.

PROFESSORS AND LECTURERS.

Greek.....	Professor J. G. GREENWOOD, B.A., Fellow of Univ. Coll., London.

The NEXT SESSION COMMENCES on the 7th of October.

Candidates for Admission must not be under fourteen years of age, and those under sixteen will be required to pass a preliminary examination in English, Arithmetic, and the elements of Latin.

Prospectuses of the several departments of the Day Classes, the Evening Classes, and the Medical School, and of the Scholarships and Entrance Exhibitions tenable at the College, will be sent on application.

J. HOLME NICHOLSON, Registrar.

PRACTICAL CHEMISTRY.

Laboratory, 60, Gower Street, Bedford Square, W.C.

Mr. Henry Matthews, F.C.S., is prepared to give instruction in all branches of PRACTICAL CHEMISTRY, particularly in its application to MEDICINE, AGRICULTURE, and COMMERCE.

The Laboratory is open daily, except Saturday, from ten to five o'clock; on Saturday, from ten till one o'clock.
Mr. Matthews is also prepared to undertake ANALYSES of every description.

For Particulars and Prospectuses, apply to Mr. Henry Matthews the Laboratory, 60, Gower Street, Bedford Square, W.C.

MECHANISM EXTRAORDINARY.

THE "SHAH,"

The Smallest Steamboat in the World, warranted to propel by steam for 15 minutes with proper attention. Price 1s., post free 15 stamps. Superior Finished, with Deck and Wire Gunwale, 1s. 6d., post free, 21 stamps.

THE "ALEXANDRA,"

Fitted with Dr. Croft's Patent Paddle and Fish-Tail Rudder, strong Copper Boiler, Bridge, &c., and steams 30 minutes in the roughest water made on the Lifeboat principle.

THE "HAVANA,"

Cigar Screw Steamboat, the marvel of the day. Price 2s. 6d., carriage paid, 3s. 6d.

Other sizes in each class up to £10, carriage extra, from 3d. to 2s. Plain directions sent with each boat. Send stamp for Price List. Models of Steamers and other vessels made to order. AGENTS WANTED.

THE MINIATURE MODEL STEAM SHIP MANUFACTURING COMPANY,
SAMPLE DEPOT, 110, LONDON WALL, LONDON, E.C.

BERNERS COLLEGE of CHEMISTRY.—
EXPERIMENTAL MILITARY and NAVAL SCIENCES,
under the direction of Professor E. V. GARDNER, F.R.S., &c.,
of the late Royal Polytechnic Institution and the Royal Naval College.

The Laboratory and Class Rooms are open from 11 to 5 a.m., and
and from 7 to 10 p.m. daily.

Special facilities for persons preparing for Government and other
examinations.

Private Pupils will find every convenience.

Analyses, Assays, and Practical Investigations connected with
Patents, &c., conducted.

For prospectus, &c., apply to Prof. E. V. G., 44, Berners-street, W.

**THE LIVERPOOL COLLEGE OF
CHEMISTRY, 96, DUKE STREET, LIVERPOOL.**

Specially Devoted to the Study of CHEMISTRY, TECHNOLOGY
and ASSAYING.

Laboratories open throughout the Year.

MARTIN MURPHY, F.R.S., &c., Principal (Successor to the late
Dr. SHERIDAN MUSPRATT).

A Special Laboratory is devoted to Commercial Analyses of every
description, and to Mineral Assays.

Manufacturers' and Smelters' Analyses and Assays undertaken on
Contract.

Patentees and Inventors Advised and Assisted. Works and Mines
Inspected. The Erection of Manufacturers' Plant Supervised, &c.

Terms and Fees VERY MODERATE.

Further Particulars and Full Prospectus on application to
The Principal, MARTIN MURPHY, F.R.S. &c.

**T. HOLT & CO.,
MAKERS OF PURE OIL & BLACK SOAPS
CHEMICALS, &c.,
FOR MANUFACTURERS AND DYERS.**

INVESTIGATION OF THE FLUORESCENT AND
ABSORPTION SPECTRA OF THE URANIUM
SALTS.

By HENRY MORTON, Ph.D.,
and H. CARRINGTON BOLTON, Ph.D.

(Continued from p. 50).

PART II.

Absorption Spectra.

THERE are in the uranium salts two sorts of absorption—one directly related to their fluorescence, and the consequence of the fact that those rays which excite fluorescence must themselves disappear, their motion indeed simply taking that other form; and the other an absorption having no such immediate relation to fluorescence, but representing rays of the spectrum whose motions are converted into heat or some other form of force not sensible to the eye. This was observed by Stokes in the case of canary glass, and in the solution of the uranium nitrate (*Phil. Trans.*, 1852, pp. 497, 517). The absorption-bands of the second variety were studied by him in crystals of the nitrate of uranium in solutions of the double carbonates of uranium, and in yellow and green uranite (*Phil. Trans.*, 1852, p. 520).

Hagenbach† has also carefully measured both classes of absorption in the case of canary glass and uranium nitrate, and points out the distinction between the first, which is correlative with absorption, and the last, which is unaffected by solution, which almost destroys fluorescence.

As regards absorptions of the first class they are best studied by direct observation, combined with a process closely allied to that described by Stokes as his *third method*, which consists in throwing a pure spectrum upon a screen of the substance in question, or upon the vertical side of a tank containing a solution. With the solid screen, the location of general maxima of fluorescence will correspond with maxima of absorption, and with the tank the absorption can be directly seen as embodied in

FIG. 3.

dark blades or triangular masses of shade running into the tank (as seen from above) from the side away from the light. These appearances will often indicate the existence and relative intensity of absorptions, whose exact location we can measure by examining the transmitted light directly with the spectroscope in the manner represented in Fig. 3.

The spectra of absorptions not directly related to fluorescence is, as a rule, best studied by transmitted light, although in the case of solids two other methods give us accordant results.

First. When observing the fluorescent bands in the usual way, if the spectroscope is directed a little obliquely towards the bottle under examination (*i.e.*, a little to the right or left of its centre), many of the absorption-bands can be readily seen. This is especially the case with the acetates, the oxalate, the calcium phosphate, and some others.

Second. If a pure spectrum is thrown upon a screen prepared with a coating of uranium salt, the absorption-bands are very distinct, and their positions may be measured as follows:—A pin-hole is made in the screen, and this is moved laterally until the centre of a band falls on the pin-hole. Then the refrangibility of the light passing through this pin-hole is easily measured by a spectroscope placed behind the screen, and gives the exact location of the centre of the band.

As an example of the accuracy of this method I will give the measurements of the absorption-bands of uranic oxalate, as measured in the light transmitted by a layer of the salt in powder attached by a little water to glass, and as determined, by the method just described, on a screen of the same substance.

Absorption-bands of uranic oxalate:—

By transmitted light ..	50° 43'	51° 07'	51° 33'	52° 00'
From a screen	50° 44'	51° 06'	51° 32'	52° 00'

The numbers here given are the direct readings on the circle of the spectroscope.* The two observations were, moreover, made at different times and by different observers, one set being made by Mr. Sorge, one of the students of the Stevens Institute of Technology. Many other measures even more accordant were obtained, but the above was selected as at once illustrating the ease and certainty of the observations by these methods. The method of measuring the bands by transmitted light has, however, always been employed in the first instance, and the other used only as a check and guide in doubtful cases.

The difference between different salts as regards their absorption-bands is very great, as a glance at Fig. 1 will show; and, while in many cases solution has a vast effect upon fluorescence, it sometimes (as Hagenbach remarked with the nitrate) produces but little effect upon the absorption-bands. In other instances, however, very marked changes occur, and, when these are followed out to their legitimate conclusions, they lead us to some very remarkable and not unimportant results. Thus, if we examine the absorption spectra of the uranic acetate and the various double acetates, we shall find that in the solid state they present great variety in the exact location of the bands, but in solution we have exactly the same spectrum for all. The conclusion naturally, therefore, presents itself, that in solution all are reduced to the same state, which could, of course, only be by the breaking up of all the double salts. Indeed, from this, supported as it is by other observations, we do not hesitate to conclude that *no double acetate can exist in solution in water*, but must break up into its two single salts. Nor do our conclusions stop here, but we must reserve others until some of the facts on which they are founded have been described. A similar experience leads us to a like conclusion in the case of the sulphates, oxychlorides, &c.

Attention was drawn to the fact of such displacement by one of us in September of last year (*American Chemist*, 1872, p. 81), but its true bearing has only been perceived recently, since a large number of observations have been accumulated.

A change of character, rather than of position, produced by solution in the absorption spectrum of didymium sulphate, was observed by Bunsen in 1866 (see *Pogg. Ann.*, vol. cxxviii, p. 100, and *Phil. Mag.*, 4th series, vol. xxxii, p. 181).

The position of the band of uranium nitrate, while un-

* Communicated by President Morton.
† *Pogg. Ann.*, 1872, vol. cxlvi, p. 396.

* In this case 1' corresponds to 4-10ths of a millimetre of the Bunsen scale.

affected by solution in water, is notably changed by other solvents, as the following table will show:—

Bands.	1.	2.	3.	4.	5.	6.
Glycerin	87.6	96.0	107.8	123.0	136.0	148.6
Water	89.8	98.5	108.5	118.7	129.5	142.0
Alcohol	—	99.4	111.7	—	—	—
Hydrochloric ether..	—	99.4	110.8	123.7	—	—
Ether	—	100.0	112.6	123.0	—	—
Acetic ether	—	101.0	111.7	128.0	135.4	—

These numbers are the averages of several sets of measurements, but the bands are in many cases very indistinct, and, in the case of the 4th band, much obscured by the Fraunhofer lines in the neighbourhood of G. The action of glycerin merits special notice, as compared with their positions in the solid; and in the aqueous solution all the bands below some point, about 110 of the scale, are depressed, while those above are elevated. Fig. 3. will make this evident at once.

A change in position of the absorption and fluorescent bands of certain organic bodies, by change of solvent, was noticed by Hagenbach (see *Pogg. Ann.*, vol. cxlvi., p. 534), and he refers to researches by Kraus, published in the *Sitzungsber. der Phys. Med. Societät zu Erlangen*, July 10, 1871, in which that observer concludes that the denser the solvent the greater the downward displacement of the bands.

Effects of Heat.

It was observed by Stokes that canary glass and the nitrate of uranium had their fluorescence largely reduced by heating, and that at a temperature much below a red-heat their influence upon light in this respect was entirely suspended. He also noticed that in the solution of uranium nitrate the same effect followed from a moderate elevation of temperature, and near 212° F. had extinguished all fluorescence. In all cases the substance regained its fluorescent properties on cooling. He also remarked that no such action appeared in fluorescent vegetable solutions.*

Gladstone has made a series of investigations on the absorption spectra of solutions, among which is one in

FIG. 4.

which the effects of heat are considered. He finds that, as a rule, the effect of heat is equivalent to a concentration of the solution, and amounts to an increase in the amount of absorption.†

In a research "On the Change of Colour produced in Certain Chemical Compounds by Heat," Prof. E. J. Houston tested, among other things, a large number of solutions, and developed the curious fact—not before noticed—that in all cases where no chemical change was involved solutions as well as solids changed to tints lower in the spectrum by the application of heat.‡

* *Phil. Trans.*, 1852, p. 532.

† *Phil. Mag.*, 1857, vol. x., p. 423.

‡ *Journal of the Franklin Institute*, 1871, vol. lxii., p. 121.

The loss of fluorescence in a few substances when heated, which was noticed by Stokes, appears to extend (with certain limitations) to all the uranium compounds, both in their solid state and in solution.

We find that in the case of the anhydrous ammonio-uranic sulphate, fluorescence is sensibly diminished at 140° C., and is almost destroyed at 260° C. The hydrate does not show any marked loss of fluorescence below the point at which it begins to part with its water. The same is true of the potassium sulphate. The sodio-uranic acetate is, however, much more sensitive. Experiments were made with it and other salts in the following manner:—A small oven was made from a piece of brass tubing, about 5" long and 1.5" in diameter, closed with caps, one of which was provided with a tubular, c. Holes of 1" diameter were cut on opposite sides, and covered with thin plates of mica, d. The salt to be examined was then placed in a small specimen bottle, into which was passed the bulb of a thermometer, whose stem traversed the tubular, in which it was packed with soft asbestos. This apparatus was then substituted for the revolving stand, c, of Fig. 4, and the heating accomplished by a spirit-lamp, while the appearance of the bands was constantly observed.

Heat being thus applied to the sodio-uranic acetate, it was observed that at about 50° C. (122° F.) the brightness of the fluorescence was reduced, and that the uppermost decided band of fluorescence (81.8) lost its distinctness. As the temperature rose the amount of fluorescence gradually diminished, until, at about 110° C., it seemed to reach a minimum. It was also evident that the bands of fluorescence were displaced downwards in the spectrum by the increase in temperature, as will be fully shown by the following table of measures made at 19° C. (66.2° F.) and 116° C. (240.8° F.). At the higher temperature the uppermost band had entirely vanished, and the lower ones were too faint for measurement with the apparatus employed.

Fluorescent bands of sodio-uranic acetate:—

Bands.	1.	2.	3.	4.	5.	6.
At 19° C. (66.2° F.)..	41.0	45.0	53.0	62.4	72.0	81.8
At 116° C. (240.8° F.)	—	—	53.0	61.0	70.8	—

No appreciable further change was produced by carrying the temperature to 150° C. (302° F.), and on cooling everything returned to its original condition. Solutions are still more sensitive in this respect. In the case of the sodio-uranic acetate, which gives a highly fluorescent solution, a very marked reduction can be perceived at 71° C. (160° F.), while at 82° C. (180° F.) there is hardly any trace of this fluorescent action left. So, again, with the ammonio-uranic sulphate in solution. Its fluorescence is first notably diminished at 71° C. (160° F.), and is almost inappreciable at 77° C. (170° F.), although it can still be seen at 88° C. (190° F.). In fact, every solution of a uranium salt which has any sensible fluorescence loses it in great part by a rise of temperature quite inside of its boiling-point.

With a number of these salts, moreover, we have noticed another curious effect, namely, a depression of some or all of their bands of absorption, as well as an increase and lowering in the general absorption which affects the upper end of their spectra.

The double carbonates furnish the most striking examples which we have yet observed, but the double sulphates show it very distinctly, as does also the oxalate.

The nitrate shows in solution a marked increase in general absorption when heated, but no displacement of bands that could be recognised. This also seems the case with the acetate and double acetates.

The table (Displacement of Absorption-Bands by Heat) will give some idea of the character of this displacement in several instances:—

DISPLACEMENT OF ABSORPTION BANDS BY HEAT.

Solution of ammonio-uranic carbonate in water :—

Bands.	1.	2.	3.	4.	5.	6.
Cold, 24° C. (75° F.)..	104.2	113.4	123.7	133.4	144.0	153.0
Hot, 86° C. (186.8° F.)	102.6	112.5	122.0	131.2	142.8	152.0

Solution of potassio-uranic carbonate in water :—

Bands.	1.	2.	3.	4.	5.	6.
Cold, 24° C. (75° F.)..	103.0	113.0	123.8	133.8	144.4	153.0
Hot, 86° C. (186.8° F.)	101.8	111.7	122.2	132.0	142.8	152.0

Solution of sodio-uranic carbonate in water :—

Bands.	1.	2.	3.	4.	5.	6.
Cold, 24° C. (75° F.)..	102.2	112.2	123.2	132.2	144.8	152.4
Hot, 86° C. (186.8° F.)	101.5	110.8	121.4	131.0	142.8	—

All these carbonates seem in solution to be without the band which is given in their solid condition at about 93.7.

Other salts also show a similar depression of absorption-bands by heat. Thus, in the uranic oxalate we have a displacement which, though small, is unquestionable, as will be seen from the following table will show.

Solution of uranic oxalate in water containing oxalic acid :—

Bands.	1.	2.	3.	4.	5.	6.
Cold, 24° C. (75° F.)..	97.5	107.8	118.4	127.2	137.2	150.6
Hot, 86° C. (186.8° F.)	97.0	107.4	117.3	125.5	136.0	148.2

The double sulphates also exhibit a like action, as will be seen from the following tables.

Solution of potassio-uranic sulphate :—

Bands.	1.	2.	3.	4.	5.	6.	7.
Cold, 24° C. ..	88.5	96.0	106.4	115.4	124.4	136.5	150.0
Hot, 86° C. ..	—	94.5	104.6	113.8	123.0	133.0	—

Solution of sodio-uranic sulphate :—

Bands.	1.	2.	3.	4.	5.	6.	7.
Cold, 24° C. ..	87.0	96.0	105.8	115.8	125.7	136.8	149.0
Hot, 86° C. ..	—	95.0	105.0	113.8	123.7	135.0	147.0

Solution of ammonio-uranic sulphate in water :—

Bands.	1.	2.	3.	4.	5.	6.	7.
Cold, 24° C. ..	87.6	96.4	105.8	115.8	124.4	136.0	150.6
Hot, 86° C. ..	—	95.2	105.0	114.2	123.4	135.0	147.4

A similar displacement we have also observed in the five absorption-bands of potassium permanganate discovered by Stokes, as the following table will indicate.

Absorption-bands of potassium permanganate dissolved in water :—

Bands.	1.	2.	3.	4.	5.
Cold 24° C. (75° F.)..	54.7	63.3	72.0	80.6	88.9
Hot, 86° C. (186.8° F.)	53.8	62.4	70.8	79.8	88.0

No displacement could, on the other hand, be detected in the bands of uranic sulphate.

Passing now from these general considerations, we will discuss in detail the various classes of salts examined, beginning with their methods of preparation.

Purification of Material for the Preparation of Salts.

Much difficulty was experienced in procuring the raw material for forming the uranium salts even in a tolerable degree of purity. The uranic nitrate and uranic oxide (so called) found at dealers in rare chemicals always contain considerable quantities of soda, iron, calcium, magnesium, and various other impurities. Some of the pure oxide employed in this research was extracted directly from uranite itself, by a process previously described by one of us,* but this proceeding was abandoned on account of the great amount of time which it consumed.

The commercial uranic nitrate is generally the purest material, but it is the least advantageous, economically speaking, since it commands the same price as the so-called uranic oxide itself.

Uranic nitrate is readily purified by solution in strong

ether, the sodic nitrate and other impurities dissolving out in the water of the ether, and forming a layer below the ethereal solution. If the ether be allowed to evaporate spontaneously crystals of uranic nitrate are obtained, but we generally preferred converting this solution directly into uranic oxide, by gently heating until the ether is evaporated and the uranic nitrate is partially decomposed; a higher heat is then applied, and maintained until fumes of nitric tetroxide cease to appear.

Care must be taken to avoid too high a temperature, which would convert the yellow uranic oxide into the green uranoso-uranic oxide: in practice we found the desired temperature is obtained by using a Wetherill burner with the full amount of gas, or a Bunsen burner so placed that the flame cannot come in direct contact with the porcelain dish: in platinum vessels it is more difficult to prevent the formation of the green oxide.

The caked mass of uranic oxide is then removed from the porcelain dish, finely pulverised in an agate mortar (no light task), and again heated until the last traces of nitric tetroxide are removed.

The commercial uranic oxide is invariably either ammoniac or sodic uranate, containing also various impurities. The manufacturers of chemicals, who prepare uranium compounds for the trade, are apparently ignorant of the fact that uranic oxide precipitated from its solutions combines with whatever alkali is employed, forming a uranate of the base, or else they knowingly dispose of these uranates as uranic oxide, for reasons satisfactory to themselves. Uranium yellow, so-called, employed by glass and porcelain manufacturers, is prepared directly from the mineral uranite, and consists of sodic uranate; possibly this gets into market as pure uranic oxide.

The pure material which forms the point of departure for the preparation of the salts named in this paper is obtained from the commercial article by the following process:—The impure alkali-uranate is dissolved in hydrochloric acid, the solution is saturated with sulphydric acid, which nearly always produces a small precipitate, filtered, boiled, oxidised with nitric acid, and then poured into a quantity of very dilute ammoniac hydrate, more than sufficient to neutralise all the acid: by this means the sodic uranate is for the most part converted into ammoniac uranate. The precipitate is well washed by decantation (using a syphon) adding a little ammoniac chloride to the wash-water when the precipitate refuses to settle, and then transferred, without bringing on a filter, to a porcelain dish. Ammoniac carbonate is then added in powder to avoid largely diluting the solution formed, and the whole is digested at a moderate heat until the ammoniac uranate is completely dissolved. The solution, filtered while warm from the residue of ferric hydrate, calcium carbonate, &c., deposits, on cooling, beautiful crystals of the double ammonio-uranic carbonate. The mother-liquid from these crystals is vigorously boiled, and deposits a yellow powder, uranic hydrate containing a small percentage of ammonia. This precipitate, however, still retains the alkaline earths and sodium, and the crystals, before obtained, show traces of sodium uranate: these impurities are removed by igniting strongly in a platinum dish, and treating the uranoso-uranic oxide formed with dilute hydrochloric acid, which dissolves out the uranates of the bases RO, while the uranoso-uranic oxide is not attacked. After washing and drying this green oxide, it is dissolved in nitric acid and the solution crystallised; the crystals of uranic nitrate are then dissolved in ether, and treated as above described.

In preparing the various compounds enumerated in the first part of this paper, we generally followed the methods laid down by the authors in their original papers; any detailed account of these methods is therefore superfluous. References to the original papers will be found in the "Index to the Literature of Uranium," prepared by one of us and published in the "Annals of the Lyceum of Natural History (New York), vol. ix., 1870.

A brief summary of some points in the preparation of

* *American Chemist*, vol. i., p. 50, 1870.

the salts will, however, be given in connection with the special discussion of each class.

(To be continued.)

ERRATA.—Page 47, first column, line 27 from foot, insert "and" between "of" and "while." Second column, line 34 from foot, for "combination" substitute "confirmation." THE CONSTITUTION OF SAFFRANIN.

By SAMUEL E. PHILLIPS.

If in such cases the men of fact and experiment are as yet dependent on speculation, it is surely legitimate to assist such endeavours by all the means at our disposal, the more so if, by placing the matter in another aspect, we can at all add to their powers of practical enquiry, on the old Baconian principle that the secrets of Nature are most freely given up to such as can enquire with humility and intelligence.

We have long regarded the rosanilin dyes as associated with the guanidin type—

Urea (CO_2) H H_2N_2
Guanidin .. H_2 Cy H_3N_2
Melanilin .. $(\text{C}_{12}\text{H}_5)_2\text{Cy}$ H_3N_2
Rosanilin .. $(\text{C}_{38}\text{H}_{16})\text{Cy}$ H_3N_2 ; $\text{C}_{38}\text{H}_{16} = 2$ atoms.

Chrysanilin .. $(\text{C}_{38}\text{H}_{14})\text{Cy}$ H_3N_2

Anilin blue .. $(\text{C}_{38}\text{H}_{16})\text{Cy}$ E_3N_2

Leucanilin .. $(\text{C}_{38}\text{H}_{18})\text{Cy}$ H_3N_2

Opal blue .. $(\text{C}_{38}\text{H}_{13})\text{CyPhH}_2\text{N}_2$

Both practical and theoretical considerations strongly enforce the idea of a condensation of atoms herein. If, instead of anilin and toluidin, the same conditions were applied to phenol and toluol, the result would certainly be a condensation, thus—

but, as variations take place by addition or subtraction of 2H, I have preferred to consider the whole group as equivalent to 2 atoms, however arranged or modified.

Chrysanilin, with 3Me replacing 3H, gives a beautiful deep orange-yellow as the iodhydrate, and rosanilin varieties have been formed, with similar aldehyd substitutions, with the radicals of almond oil (C_{14}H_5), enanthol ($\text{C}_{14}\text{H}_{13}$), valerol (C_{10}H_9), &c.

Melanilin is produced by the action of cyanogen upon anilin, and when rosanilin is heated with "cyanogen, it loses colour, and deposits a new base with 4N which is regarded as leucanilin in which 1H is replaced by Cy." This is called hydro-cyan rosanilin, and this we now moot as the type of saffranin and mauvin.

The production of saffranin from azo-diamines is another illustration of the condensing conditions we have referred to—

Hydro-cyan rosanilin .. $(\text{C}_{38}\text{H}_{18})\text{Cy}_2$ H_2N_2

Saffranin $(\text{C}_{38}\text{H}_{18})\text{Cy}_2$ H_2N_2

Mauvin $(\text{C}_{38}\text{H}_{18})\text{Cy}_2\text{PhH}$ N_2

Are these (3 atoms in 2) varied in this case isomerically, or is the beautiful orange-yellow cyan-rostanilin iodhydrate identical (in its base) with the deep red-yellow saffranin chlorhydrate?

The cyano-production of all these bodies is feasible beyond measure synthetically; and may we look for some new efforts to realise this point analytically?

Whatever be the result, one thing is quite clear, viz., that all these bodies are defiant of the Hofmann law of ammonia combinations. Whether diamines as I view them, triamines, or tetramines, they obey a simpler wider law, and combine with acids, atom for atom—

The free base .. $(\text{C}_{38}\text{H}_{18})\text{Cy}_2\text{H}_2\text{N}_2$

Chlorhydrate .. $(\text{C}_{38}\text{H}_{18})\text{Cy}_2\text{H}_3\text{N}_2, \text{Cl} + \text{HCl}$

Chloroplatinate .. $(\text{C}_{38}\text{H}_{18})\text{Cy}_2\text{H}_3\text{N}_2, \text{Cl} + \text{PtCl}_2$

Nitrate $(\text{C}_{38}\text{H}_{18})\text{Cy}_2\text{H}_3\text{N}_2, \text{O} + \text{NO}_3$

Hofmann further refers to the sulphate, oxalate, &c., all of which doubtless similarly conform.

Magdala is another red dye which may possibly belong to the same character of type, constitution, and general properties. Some years ago, Perkin and Church obtained "a beautiful crystalline compound, consisting of 2 atoms of naphthylamin linked together by an atom of trivalent N—

and subsequently M. Clavel, of Basle, patented a process for a beautiful crimson dye "heating together equal quantities of isomeric naphthylamin, acetic acid, and nitrite of potassium." This can now be obtained from ordinary naphthylamin and "an acid, by a process similar to that of rosanilin from anilin, and we thus get magdala—

and, in boiling the first with anilin, we evidently get—

another red colouring matter."

Rosanilin $(\text{C}_{26}\text{H}_{11})(\text{C}_{12}\text{H}_5)\text{CyH}_3\text{N}_2$
Perkin and Church .. $(\text{C}_{20}\text{H}_7)(\text{C}_{18}\text{H}_5)\text{CyH}_3\text{N}_2$
Magdala $(\text{C}_{40}\text{H}_{13})(\text{C}_{18}\text{H}_5)\text{CyH}_3\text{N}_2$
Red colouring matter .. $(\text{C}_{40}\text{H}_{13})(\text{C}_{12}\text{H}_5)\text{CyH}_3\text{N}_2$

In the last two I have, for reasons before mentioned, assumed the naphthyl element as a dinaphthyl, which is not a mere hypothetical body; but, if preferred, it may be regarded as $(\text{C}_{20}\text{H}_7)_2(\text{C}_{18}\text{H}_5)\text{CyH}_3\text{N}_2$. Against this latter view I would urge that, as we have an ethyl-mauvin, so we might have ethyl, methyl, or aldehyd replacements of both saffranin and magdala, and these might show whether we have 2 or 3 atoms of H available for these replacements.

Having felt some interest in writing this short notice offhand, I laid it down with a strong feeling of dissatisfaction, in that it fell so far short of what seemed to be desiderated in regard to the condensing conditions implied in the multifarious production of azodiamine, nitrite, and other bases. The refined labours of Gries, Hofmann, and others, have produced a very wide harvest of facts, and some great effort is needed in the direction of a simple and comprehensive classification.

This new and fertile character of reaction comes in contact at several points with anilin, or rather coal-tar, production; at another moment we are penetrating the indigo or kreatinin series; while, at another point, we are immersed in caffein or uramin derivatives; and it is almost beyond question that, in the whole of these, a certain amount of carbon is condensed into the cyanogen atom. But the cyano aspect is only one feature of the reaction, and the other, most relied upon in our estimate of saffranin, meets with a striking confirmation in another memoir from that fertile pen which has laid us under such deep obligation. We may cavil at certain points of hypothesis or type-representation; but for a commanding genius, for one who penetrates so successfully into unknown regions, there can be only one award of universal

esteem and admiration. We therefore continue the subject by a brief abstract of M. Hofmann's paper (CHEMICAL NEWS, vol. xxvii., p. 1), "On the Synthesis of Aromatic Ammonias by Atomic Interchange." He found that the action of methylic alcohol on anilin, at high temperature and pressure, is far from producing methyl- and dimethyl-anilin exclusively, as hitherto believed, and that the substitution takes place in the phenyl radical, thus producing quite a series of higher homologues. He thinks the replacement of the Me takes place first in the fourth atom of H "in the chlorhydric acid of the anilin salt," then in the others, and finally in the phenyl radical itself, but moots it as strange that, when a tertiary monamine is submitted to the action of an alcoholic chloride, a quartary ammonium is invariably found; and yet, in the above process, only tertiary, and never any quartary, bases are observed.

In the praiseworthy "endeavour to gain an insight into the mechanism of this reaction," M. Hofmann assumes what is perhaps unnecessary, and strangely overlooks the patent facts of the condensing conditions, and the evolution of H in the substitutional condensation of the phenyl radical. The phenyl element ($C_{12}H_5$) becomes—

Ordinary action ($C_{12}H_5$)Me₂N + MeCl =
($C_{12}H_5$)Me₃N, Cl
Do. with heat and pressure . . ($C_{12}H_5$)Me₂N + MeCl =
($C_{14}H_7$)Me₂NN, Cl

His illustration of the real facts of the case is plain beyond measure:—"Accordingly, trimethylated ammonium iodide, submitted to the action of heat and pressure, is transformed into—

- (1) Dimethyl-toluidin iodhydrate . . ($C_{14}H_7$)Me₂H N, I
- (2) Methyl-xylidin iodhydrate . . . ($C_{16}H_9$)Me H₂N, I
- (3) Cumidin iodhydrate ($C_{18}H_{11}$) H₃N, I"

Here, then, is one of the first formal demonstrations of the action we have mooted as the secret or chief feature in the production of rosanilin or safranin varieties, and guided by a parallel study of the same influence, we confidently predict the imminent artificial production of their or caffeine, of which more anon.

CARBOLIC ACID AND ITS RELATION TO CREASOTE.*

By A. M. READ.

CARBOLIC acid was discovered in the year 1834, by Runge, who found it to be a constituent of coal-tar oil. Its chemical properties were more thoroughly investigated in the year 1841, by Laurent, who made it from the lighter oils of coal-tar, and who considered it to be an hydrated oxide of a peculiar compound radical, which he called phenyl, and described it under the name of hydrate of phenyl. It has been variously named by different writers, phenic acid, phenyl alcohol, hydrate of phenyl, coal-tar creasote, carbolic acid, and phenol, the latter of which is the name under which it is generally treated of in textbooks, although carbolic acid is and probably ever will be its common name.

Carbolic acid is produced by the action of nitrous acid on anilin, and by the dry distillation of gum benzoin, quinic acid, chromate of pelosina, salicylic acid, coal, and the resin of *Zanthorrhæa hastilis*. It is found in the urine of the horse, cow, and man, and in castor. It is also reported as having been obtained from a plant growing on the high lands of India (the *Andromeda Leschenaultii*), which is said to yield† a very pure quality, less deliquescent

than that made from coal-tar oil, but at a much greater cost. It forms the chief constituent of the acid portion of coal-tar oil, from which it is generally obtained by the process given below.

The coal-tar oil is subject to distillation in a retort furnished with a thermometer, and the portion that passes over between the temperature of 150° and 200° C. (302° and 390° F.), is collected apart. This product is then mixed with a hot strong solution of caustic potash and left to stand, whereby a whitish, somewhat crystalline pasty mass is obtained, which, by the action of water, is resolved into a light oily liquid and a dense alkaline solution. The latter is withdrawn by a syphon, decomposed by hydrochloric acid, and the separated oil purified by contact with calcium chloride, and re-distillation. It is then exposed to a low temperature, and the crystals formed are drained from the mother-liquor and carefully preserved from the air.

Pure carbolic acid forms long colourless prismatic crystals, which melt at 35° C. (95° F.), to an oily liquid, boiling at 180° C. (356° F.), and greatly resembling creasote in many particulars. It is soluble in about 14 parts of water, freely soluble in alcohol, glycerin, ether, and strong acetic acid, and gives no acid reaction to test-paper. It is very deliquescent, absorbing moisture from the atmosphere with avidity and liquefying. It coagulates albumen readily, and is therefore a powerful antiseptic. Sulphur and iodine dissolve in it. Nitric acid, bromine, and chlorine attack it with energy, forming substitution products, all of which are of an acid character. It also forms substitution products with sulphuric acid, and is dissolved by alkalies, forming salts called phenates. It reduces mercuric oxide at the boiling point; separates silver from the nitrate; reduces the peroxide of lead to the protoxide; and upon heating it with arsenic acid forms a yellow substance called xanthophenic acid. One of the most common impurities found in carbolic acid is coal-tar oil. This can easily be detected by mixing the suspected acid with about 20 parts of water, when the acid will be dissolved, leaving the insoluble oil floating on the surface. Pure carbolic acid gives a pure blue colour to pine wood previously treated with hydrochloric acid; a green colour indicates aniline, and a brown pyrrhol. It ought not to turn brown in the air, even in the presence of ammonia; and should give, with sulphate of iron, not a red but a pure lilac colour. When immersed in an aqueous solution of chromic acid it is immediately turned black.

There have been a great many tests given to distinguish creasote from carbolic acid; but none of them have proved satisfactory. I give below some of the principal ones now used for that purpose.

With three or four volumes of a saturated aqueous solution of baryta, carbolic acid forms a clear solution, which, after standing, gives no deposit, or only a slight pulverulent one, while with creasote it forms an incomplete cloudy solution.

With an alcoholic solution of chloride of iron, creasote gives a green colour, carbolic acid a brown; but with an aqueous solution of the same, creasote gives no reaction, while carbolic acid gives a blue colour.

According to Mr. Morson, pure creasote is insoluble in glycerin, while carbolic acid forms with it a perfectly clear solution. As this test has been the subject of some controversy which has attracted considerable attention, I have made a few experiments with it, the results of which I give below.

I first tried the common creasote of commerce with an equal volume of glycerin, and found it to be readily soluble; Merck's gave the same result, but Morson's refused to dissolve in glycerin, sp. gr. 1.253, even after three or four volumes had been added.

I then carefully added carbolic acid to a mixture of Morson's creasote and glycerin, and found that upon the addition of 23 per cent of Calvert's No. 2 acid the creasot

* Read before the National College of Pharmacy, Washington, D.C.
† From its volatile oil, of the composition of oleum gaultheriæ.—*Ed. Am. Journ. Pharm.*

became soluble, forming a perfectly clear solution with the glycerin.

Upon the addition of water to the three solutions of creasote, they each became cloudy, and the creasote soon separated; while upon a solution of carbolic acid in glycerin, water had no effect whatever.

Some time ago, while preparing a catarrh mixture in which carbolic acid is used in conjunction with liquor ammoniæ fortior, alcohol, and water, I found that upon the addition of the ammonia to the acid, the acid was readily dissolved, forming a clear solution, which did not change upon the addition of the other ingredients; but which, after standing a few hours, became a beautiful violet blue colour. Having been taught by text-books that carbolic acid was insoluble in ammonia, I was somewhat surprised at this result, and upon referring to Watts, Gmelin, and other authorities, and finding that they made the same statement,* my surprise was somewhat intensified: I immediately instituted a series of experiments, and found that carbolic acid was certainly soluble in ammonia, but whether owing to impurities present I could not say. I used Calvert's No. 2 acid, which was immediately dissolved by the ammonia, forming a clear solution, which, upon standing about six hours, gave the violet blue colour spoken of above, the acid still remaining in solution, and giving no precipitate.

I then tried the ammonia upon common creasote, which I found to be insoluble in it, but which, after a short time, acquired a light blue colour.

To carry these experiments to a successful issue, it became necessary to procure chemically pure carbolic acid and creasote. After a number of attempts I succeeded in getting Morson's and Merck's creasote, and having in the meantime found in the *Druggists' Circular* a process for purifying carbolic acid, which, with some modifications, I have used, I have succeeded, I think, in confirming my first experiments.

I will give the process of purification as used by myself. I put into a pint flask 1 oz. of Calvert's No. 1 acid, crystallised, and gradually added 10 ozs. of distilled water, shaking it frequently, when I found that 6½ drachms of the acid were dissolved, leaving 1½ drachms undissolved to contain the impurities, which are less soluble than the acid. As soon as the solution became clear I carefully poured it off, placed it in a hydrometer glass, and added, with constant agitation, finely powdered salt (previously purified by dissolving it in water, filtering the solution, and evaporating to dryness), until the water was saturated, and the acid arose to the top. I then carefully removed the acid with a pipette. Upon the addition of ammonia to this product it was very readily dissolved; but it did not give the violet-blue colour until after standing about twelve hours. Not being satisfied, I re-purified it in the same way, being careful not to add as much water as I did at first.

The addition of an equal volume of ammonia to this product of re-purification quickly dissolved it, forming a perfectly clear solution, which did not acquire the violet-blue colour until standing nearly thirty hours.

For want of time I was not able to carry the purification by fractional distillation as I should like to have done; still I consider the product of re-purification very nearly

pure—much purer, at least, than any I could find in the market.

Upon the addition of ammonia to this acid, as stated above, it was readily dissolved; while, upon Morson's creasote, ammonia had no effect whatever, neither dissolving it nor giving it the blue colour that it gave to the common creasote. Merck's creasote gave the same result; it as well as other samples that I have tried being perfectly insoluble in ammonia.

The ammonia used in the experiments given above was the aqua ammoniæ fortior of the U. S. P., sp. gr. 0.900. The aqua ammoniæ U. S. P., sp. gr. 0.960, would answer the same purpose, but a much larger proportion would be required.

After the successful termination of the experiments given above, I have no hesitation in suggesting aqua ammoniæ fortior as a test to distinguish between carbolic acid and creasote; and of leaving its value as compared to other tests now known to the judgment of the pharmacist and chemist.

IRON ELECTROTYPES.

THE art of electrotyping, already applied to myriad uses, shows constant evidence of progress, especially in the successful deposition for practical purposes of metals that have hitherto been considered intractable. Nickel plating is now common, and, while cheaper, is for some purposes superior to silver; and there is some reason to suppose that by the employment of a small percentage of some other metal to diminish the brittleness, the rather refractory nature of the nickel coating may be brought more completely under the control of the burnisher in lieu of the polishing wheel, than is now the case. There are many purposes, however, for which a plating of iron would be, all things considered, better than any of those now familiar in electro-metallurgy, and to secure this has occupied the attention of some foreign experimenters, who have apparently been very successful in their efforts. These are described in a lengthy article in a number of *Engineering*, from which we take the following:—

"At the late London International Exhibition (1871) were exhibited bank-note plates, medallions, and a page of printing-type, electrotyped in iron by a process devised by M. Eugene Klein, who is at the head of the Chemical Department in the Imperial State Paper Manufactory in St. Petersburg. From a paper upon the subject, read by Professor Jacobi before the Academy of Sciences in Russia, in 1868, it appears that in the previous year M. Feuquières sent to the Paris Exhibition some specimens of iron electrotype which presented a fair appearance as regarded surface, but still were inferior to those produced by M. Klein in the year following. M. Klein saw M. Feuquières's specimens at the Paris Exhibition, and on his return to St. Petersburg, in October, 1867, renewed his previous attempts to electrotype in iron. The scientific interest which attached to the new development, and the eminently useful applications of which he saw it was susceptible, especially in the departments of engraving and printing, stimulated M. Klein, and in the early part of 1868 he had accomplished his object. The medals produced in the early part of M. Klein's researches showed on their reverse porosities and deep hollows, which penetrated nearly through the thickness of the deposit. These cavities were also observable in great numbers in the productions of M. Feuquières. In M. Klein's later specimens these singular cavities—which probably proceeded from bubbles of gas—entirely disappeared, and their reverses are in no way inferior to those of copper specimens produced under the best conditions. The starting-point of M. Klein was the steeling of engraved copper-plates, which process was effected in a bath composed of the chlorate of ammonia and iron, to which he added a small

* Note by the Editor of *Am. Journ. Pharm.*—Gmelin's "Hand-book," edition of Cavendish Society, vol. xi., p. 150, contains the following:—

Carbols of Ammonia.—Carbolic acid absorbs ammoniacal gas abundantly and with evolution of heat, forming carbols of ammonia (Laurent, Hofmann, *Ann. Pharm.*, 47, 75). This salt, passed in the state of vapour through a glass tube at a low red heat, deposits a small quantity of charcoal, but does not form any aniline; which, however, is formed at 300° C. in sealed tubes, and sparingly when an alcoholic solution of carbols of ammonia is set aside for a month (Laurent). Strong ammonia dissolves quickly in coal creasote, and the mixture turns red when exposed to the air (Reichenbach). The salt obtained with carbolic acid remains colourless, and even when it contains but little ammonia, exhibits alkaline reaction, exhales ammonia, and volatilises (Runge). Creasote dissolves in ammonia, even in the cold; and the solution gives off all its ammonia at 200° (Gorup-Besanez).

portion of glycerin. Those, however, who have paid attention to the steeling process have had occasion to remark that in giving the deposit of iron a greater thickness, the surface cracked, and the deposit detached itself from the cathode in excessively brittle flakes. It became necessary, therefore, to employ baths of two different classes, composed of sulphate of iron and sulphate or chlorate of ammonia. Finally, M. Klein devised three baths after the formulæ $\text{FeO}, \text{SO}_3 + \text{NH}_4\text{O}, \text{SO}_3 + 6\text{HO}$.

"The first bath consists of a concentrated solution of crystals of the double salt $\text{FeO}, \text{SO}_3 + \text{NH}_4\text{O}, \text{SO}_3 + 6\text{HO}$ above mentioned. The second bath was composed by mixing the concentrated solution of each of these two salts in the proportions of their equivalents. At length M. Klein obtained the third bath by taking a solution of sulphate of iron, precipitating the iron by carbonate of ammonia, and dissolving the precipitate by sulphuric acid, getting rid of all excess of acid. In preparing the baths of the second class, M. Klein, as we have stated, mixed the solutions of chlorate of ammonia and sulphate of iron in the proportions of their equivalents. Another method employed is to dissolve, in a solution of sulphate of iron, as much chlorate of ammonia as it will readily absorb at a temperature of about 66°F . All these baths were concentrated as highly as they could be. As an anode, M. Klein employed iron plates giving a surface of about eight times that of the copper cathode. In using a Daniell battery for the decomposition, the deposit was formed in twenty-four hours upon the whole of the cathode. The deposit, however, was full of flaws, and was easily detached and broken up into fragments. As it often happens that the solution of sulphate of copper improves by use, M. Klein hoped that the iron solutions would act in a similar manner. He therefore continued the experiments for several days, without, however, obtaining any better results. Under the advice of Professor Jacobi, instead of a pair of Daniell cells for each of the five stages of decomposition, he then employed four pairs of feebler Meidinger cells, uniting them in series with the five stages of decomposition. This arrangement was found to give a smaller development of hydrogen at the cathodes, and better final results. The deposits, however, were not yet perfect, some exhibiting porosity, and others being furrowed.

"Conceiving from previous experience that this was due to acidification of the bath, M. Klein tested it, and found a very decided acid reaction. He attributed this acidification to the circumstance that the quantity of iron deposited on the cathode was greater than that dissolved by the anode. It was, therefore, necessary to give the anode a greater degree of solubility, and as that could only be affected by increasing its area, M. Klein conceived the idea of placing in the bath a plate of copper, and uniting it with the iron. The result of this combination was very remarkable; not only were the baths of the first class rendered neutral after several hours, but the deposits became much more uniform. Their colour was a dull grey; they adhered perfectly to the cathode without warping or cracking any part. During the first twenty-four hours the surfaces remained perfectly even, but afterwards they began to exhibit minute cavities similar to the appearances often produced upon galvanic deposits of copper. These cavities, however, rarely penetrate to the depth of the deposit. Their production is attributed to the superabundant disengagement of gas on the surface of the cathode. It probably happens that these bubbles attach themselves strongly enough to hinder the formation of the deposit. If the energy of the current becomes too great, these annoying phenomena are produced more frequently. By reducing this energy in the process, and having only an imperceptible disengagement of gas, by diminishing the concentration of the bath, or augmenting the resistance of the solid portions of the circuit, the formation of these cavities entirely disappeared, and the beautiful results to which we have already referred have been obtained. A microscopical examination of the reverses of the deposits produced by M. Klein's final process

fails to discover any porosity or irregularity in the specimens. On leaving the bath, the iron is as hard as tempered steel, and very brittle. Re-heated to a dull red heat, it loses much of its sharpness and hardness. Heated to a cherry-red, it becomes malleable, and may be engraved as easily as soft steel. If the deposits are produced in good condition, and annealed uniformly and with the necessary precautions, they are subject to neither warp nor bend. There is no contraction, but, on the contrary, a slight degree of expansion, almost imperceptible, however. Owing to the necessity of having bank-note and similar plates identical in every respect, it is of the first importance that they should not be distorted, nor have their dimensions altered in the process of annealing. It appears that the galvanic deposit of iron has not only permanent magnetism, but that, like soft iron, it receives the magnetism of position. Of the importance of the practical application of the process there can be no doubt whatever. By replacing plates of copper by those of iron, greater facilities will be afforded for producing publications, works of art, and especially bank-notes and cheques. Iron electrotype plates are found to be almost indestructible. They not only can be printed from an almost unlimited number of times, but they are better calculated than those of copper to withstand those inevitable accidents constantly occurring in printing establishments. Printers are sometimes obliged to set aside as useless their best plates, which are often damaged by a grain of sand or by a chance knot in the paper. These accidents not only involve the expense of renewing the plates, but sometimes occasion interruptions and delays in works of a very pressing nature. These are some amongst the many advantages which may be expected to accrue from the introduction of iron electrotypes."

ON THE ENERGIES OF THE IMPONDERABLES, WITH ESPECIAL REFERENCE TO THE MEASUREMENT AND UTILISATION OF THEM.*

By the Rev. ARTHUR RIGG, M.A.

(Continued from page 106.)

Now, to examine these muscles—their fibres and their fibrillæ, to watch their action, and to speculate upon the causes of this action, is a department of science full of interest, and from which much that is valuable may be brought. The object of this lecture does not require that any such investigation should be made, and the competency of the lecturer is not equal to the task. Dr. Haughton, of Trinity College, Dublin, has for many years sought for means and opportunities, and availed himself of them, even at the risk of his own life, for determining accurate measurements of muscular force. This first mention of the name of one who for twelve or fourteen years has given that attention to this subject which enthusiasm alone could induce, must not be passed without this addition. In reply to a letter towards the close of 1872, Dr. Haughton most kindly sent me 400 pages of the proof sheets of a work on "Animal Mechanics," which has not yet been published.† This work is my authority for the figures relating to the experiments in respect to muscular strength and endurance. With the results his careful and numerous opportunities have afforded him we are clearly concerned. How carefully these have been

* The Cantor Lectures, delivered before the Society of Arts.

† Since the delivery of this lecture the work has been published, under the title of "The Principles of Animal Mechanics," by the Rev. Samuel Haughton, F.R.S., Fellow of Trinity College, Dublin. London: Longmans, Green, and Co. Dr. Haughton states in the preface that "the work is offered to the public with the view of showing the mutual advantage obtainable by anatomists and geometers from a combination of the sciences they cultivate. Anatomists will gain by the increased precision which numerical statements must give to their observations, and geometers will find in anatomy a new field of problems opened out to their investigations."

collected may be judged from the following. He writes, "This much I can guarantee, all the dissections, weighings, and observations have been made by my own hands, with every precaution of which I could think to ensure accuracy. My observations have also been made without preconceived hypothesis to guide them; and many of my most interesting results have been forced upon my notice by the facts placed before my eyes in the dissecting room and laboratory."

First, as to the expression "coefficient of muscular force." On the wall is a table of "coefficients of muscular force."

In the arm	94.7 lbs. per square inch.
" leg	110.4 lbs. " "
" abdomen	107.0 lbs. " "

Average 104.0

The term "coefficient" is a word of common occurrence in scientific investigation, and is plainly obtainable from "coefficientcy." When we speak of coefficientcy we mean "that two or more things combine to produce an effect." It is the figure by which a unit measurement is multiplied in order to produce a result. To find the coefficient of muscular force is to find some quantity which may be so combined with a measured area of muscle as that we can have a result on which to rely in reference to the question proposed. Adopting the view which the lectures on energy and gravity propounded, it may suffice for the present to say that the table on the wall tells us that, knowing the number of square inches contained in the cross section of any muscle, then multiplying these by the figures there stated, we obtain the weight which the particular muscle can, on sudden emergencies or for a very short space of time, sustain. It is the limit of endurance—it is the measure of lead which is just sufficient to cause the muscle to break—if a small weight more be added then the muscular fibres will be broken. It is the very extreme tension to which muscular fibre may be subjected without actual rupture. It is obtained by treating muscle as engineers treat wrought-iron rods when they seek to ascertain what load they can carry by tension. This explains that the table does not give a coefficient of work the muscles can do; such a coefficient depends upon the energy that vitality (or vital force, if the term be preferred) can infuse into the muscle; but, however great that vital power may be, the work done by the muscle must be less than that obtained in the table to which these remarks apply. A few words in illustration may not be misplaced.

We find from experiments, which would occupy far more than an hour to narrate, that in order really to tear 1 square inch of muscle across, it would require 94.7 lbs. in the arm, and in the leg 110.4 lbs. It is somewhat remarkable that in the arm, which does not carry the body, you have 94 as the strength of the muscle. When you come to those connected with the leg, which have to carry the body as well as do work, the fibres are very much stronger. Taking the average of the whole body, the coefficient of 1 square inch of muscle in the human frame is 104. Therefore if we know the size of any particular muscle and multiply it by 104, we get in lbs. weight the limit of strain it will endure before fracture.

Now the next question is, how much it will raise. In this view of the case motion enters. Supposing a fibre was in the form of a string, a very long one, and by contracting it will raise 2 lbs. weight through 10 feet. If, now, that fibre were doubled and only half the length, it would raise 4 lbs., but it would only lift it through half the space, because its power of contraction would be diminished by the doubling. Now, the products of the weight raised, and the distance through which it is raised, are the same in both cases. If it raises 2 lbs. through 20 feet, 40 would be the measure of that muscular exertion; and if it raised 20 lbs. through 2 feet, 40 would still be the measure; but the distances are different. After illustrating experimentally these statements, the

lecturer remarked that if an ounce of muscle be distributed with large sectional area, then its contraction will be little, but the weight raised may be great.

Muscle has also another peculiarity different from anything with which we can deal. If a bundle of it be taken, as you are aware, it acts by contraction; but while it contracts it does not change its bulk. It does not swell out as we understand the word—it merely contracts. Thus, if you had a long muscle acting in a vessel of water, and it contracted ever so powerfully, it would not in the slightest degree affect the level of the water in the vessel.

Now we come to the mode in which the mechanical action of these combined muscular fibres is to be brought to a question of simple calculation. As far back as 1798 Dr. Wollaston occasionally observed a peculiar sound in his ears, for which he could not account. He pondered over this sound until about 1808, when a faint dawn began to enlighten the gloom. In 1809 he made clear to his friends what he was about, and in 1810 the results were published in the *Philosophical Transactions*. What he then did is the basis of all our present knowledge of this subject of muscular power.

Dr. Wollaston began to surmise that the sound in his ears arose from muscular contractions. He stated that he was led to infer the existence of intermittent contractions, from a sensation perceptible upon inserting the extremity of a finger in the ear. A sound is then perceived which resembles most nearly that of carriages at a great distance passing rapidly over the pavement. The sound is not dependent upon the degree of pressure upon the tympanum, for when the ear is stopped with great force without the presence of muscular action no such sound is produced. For instance, if the head press with its whole weight upon the ball of the thumb no noise is perceived unless the extremity of the thumb be at the same time pressed against the head, or some other muscle be brought into play. To judge of the frequency of this contractile action, he contrived to imitate the sound and to render the sound itself and the imitation audible by the same ear. It was accomplished thus. While the ear rested on the ball of the thumb the elbow was supported by a board lying horizontally, in which were cut notches about $\frac{1}{4}$ inch asunder similar to those in this board. By rubbing a pencil along these notches with a regular motion he imitated pretty correctly the tremor produced, and by counting the marks and noting the time, he found repeated observations agree with each other as nearly as could be expected. He also varied the experiment. One variety was this—the ear was stopped by a cushion pressed upon by the end of a notched stick that rested on his foot and conveyed the vibrations from the muscles of the leg to the ear along with the tremor produced by friction upon the notches; and still the results were nearly the same, viz., that the muscular vibrations resembled the sound of carriages at a distance. He induced many friends to repeat the experiments, and by going through the form of the experiment any one may, when convenient, satisfy himself. The humming sound will, of course, be perceptible only to the ears of the experimenter.

Put the first finger of each hand to the ears, not pressing them tightly, resting the elbows on a table thus, and then clench the fists firmly, you will immediately throw the muscles of the arm into action, and as soon as they are brought into action there is a peculiar humming sound perceptible. That is a sound caused much as the sound of flies, when buzzing about, is caused, or as humming birds cause their sound; it is caused by an intermittent action; in this case of the muscles, and upon that action, the rest of this lecture will turn. There is, however, a better plan even than that for observing this phenomenon. When you go to bed, if you are particularly bent on scientific research, and will lay your head on the pillow so as to entirely exclude all external sounds from the ear, then clench the teeth firmly, those muscles which are concerned in masticating the food are brought into play, and you hear the sound most distinctly. Now, that

sound gives a musical note, and from that musical note all our knowledge of muscular action springs. All musical notes are caused by the frequent repetition of a vibration at equal intervals. Here is a glass tube of some length, and a little jet of gas lighted. If the tube be placed over the gas-light you hear a musical note. That is caused by the light being extinguished and re-lighted a certain number of times per minute, as you can see by watching the reflection in the mirror. If, now, the mirror be shaken behind the light, a number of separate flames appear, if these are counted we can ascertain how often they occur in a minute or an hour. Therefore we know the number of beats which produce that musical note. Here is an instrument for causing a sound by the frequent interruption, at equal intervals of time, of a stream of air. The number of interruptions in a given time are recorded by the wheel-work and indicated on these dials. It is called a "Siren." Again, here is a gyroscope, which does the same thing. If some string be wound round, and it is set in rapid rotation, and then a piece of cane or quill be pressed against the little wheel at one end of the axle, the note produced will vary according to the speed of the rotation. Another illustration may be had from the heating of metals of certain peculiar-shaped surfaces, and laying them on cold metal,—sometimes a peculiar humming sound is heard.

When Dr. Haughton was suffering from a singing in the ears after an attack of fever, he produced a sound by exercising the muscles of the jaws; this sound was in unison with the singing in the ears, but separated from it by several octaves. Dr. Haughton was struck, like Dr. Wollaston, with the resemblance of the sound to distant cabs. He measured the intervals of the granite pavement, and found them about 4 inches apart. This gave three impulses in the foot. If the cabs were driven at 8 miles per hour we have 35.2 impulses per second. An organ-pipe with a movable stop was tuned in unison, and thus 35 1-3 vibrations per second were deduced.

From this rate of muscular contraction Dr. Haughton deduces the amount of work stored up in human muscles. It may facilitate an explanation of the table and diagrams on the wall if, in as simple and clear a manner as in my power, the mode of conducting the experiments is described. Remember the object is to make clear to all not only the mode, but also the principles on which these experiments rest. Therefore every technical or professional term must, as far as possible, be avoided.

(To be continued).

MISCELLANEOUS.

University of London—First B.Sc. and Preliminary Scientific M.B. Examinations.—The following are lists of candidates who have passed the recent Examinations for Honours:—*Mathematics and Mechanical Philosophy* (First B.A. and First B.Sc. conjointly).—First Class. M. J. M. Hill, First B.A. (Exhibition), University College. Third Class. J. Edwards, First B.A., Owens College, and W. Fawcett, First B.A., private study (equal). *Chemistry* (First B.Sc. and Preliminary M.B. conjointly).—First Class. C. M. Thompson, First B.Sc. (Exhibition), University College; J. V. Jones, First B.Sc., University College; G. Christopher, First B.Sc., University College; P. P. Bedson, First B.Sc. and Prel. Sci., Owens College. Second Class. D. R. Jones, Prel. Sci., University College; S. A. Hill, First B.Sc. and Prel. Sci., Royal School of Mines; H. Davy, Prel. Sci., Guy's Hospital; H. Robson, First B.Sc. and Prel. Sci., University College. Third Class. W. Banks, Prel. Sci., private study; A. Daniel, Prel. Sci., University of Edinburgh, and J. W. Meek, Prel. Sci., Owens College (equal); C. Hopkinson, First B.Sc., Owens College, and O. J. Lodge, First B.Sc. and Prel. Sci., private study, and J. Ryley, Prel. Sci., University College (equal); W. P. Mears, Prel. Sci., London

Hospital; T. F. Harris, First B.Sc., private study. *Experimental Physics*.—First Class. O. J. Lodge, First B.Sc. and Prel. Sci., private study. Second Class. H. Sainsbury, Prel. Sci., University College. Third Class. D. R. Jones, Prel. Sci., University College; J. V. Jones, First B.Sc., University College. *Organic Chemistry, and Materia Medica and Pharmaceutical Chemistry* (First M.B.).—First Class. A. H. Jones (Exhibition and Gold Medal), Guy's Hospital; A. J. Pepper (Gold Medal), University College. Second Class. T. K. Rogers, University College; C. L. Jones, Guy's Hospital, and E. W. White, King's College.

CORRESPONDENCE.

THE NESSLER REACTION.

To the Editor of the Chemical News.

SIR,—The Nessler reaction appears very unmanageable in some hands; you will therefore probably admit the value of the following simple suggestion:—In diluting the stock standard sulphate of ammonia solution, and also in making the Nessler comparisons, use, instead of pure distilled water, distilled water which has been recently boiled after the addition of some caustic potash.

This is a ready means of getting water free from ammonia, and considerably heightens the sharpness of the comparison texts. I have adopted the plan some years.—I am, &c.,

SIDNEY W. RICH.

Laboratory, 1A, Chenies Street, W.C.

NOTES AND QUERIES.

Anthracen.—In experimenting with this substance I endeavoured to prepare the pure material by sublimation from the residue left on digesting crude anthracen in alcohol (sp. gr. 823), which residue contains 90 to 100 per cent pure anthracen. In this way I obtained a product, yellowish-white and snow-like, being exactly like the anthracen which crystallises from benzol (90 per cent), but on testing its melting-point, I found it to be below 180° C., instead of 210° C., the melting-point of pure anthracen, according to most authors. What explanation to give for this I really do not know, unless it is that the product is a mixture of anthracen and naphthalin, but the latter body should have been completely washed out, 400 c.c. of alcohol having been used in washing only 20 grms. of the crude pressed anthracen, and of this, after washing and drying, only 6.8 grms. of insoluble matter remained. At the same time I obtained, as I have repeatedly in other experiments, a most beautiful cluster of thin, iridescent, transparent plates: these I have often found attached to the under surface of the filter-paper on which I have been drying anthracen. I shall be glad, if any other readers of your valuable paper have made similar experiments, if they will forward their results and inferences. On a future occasion I shall have great pleasure in sending an account of any other experiments I have made on anthracen which will be more worthy of publication than this short account may be.—T. H. D.

Notes on the Utilisation of Sewage.—

97. (To Mr. Bazalgette). What is the total amount in tons of the sewage of the northern side of the Metropolis?—The sewage on the north side is altogether 87,000,000 gallons per diem.

98. (To the same). How much would be in a year?—It is probably worked out pretty correct in page 106 of this report of the Main Drainage Committee, where it is stated the annual volume of the sewage on the north side amounts to 36,967,285,300 of gallons.

99. How many tons would that be in the year?—168,033,115 tons.

104. (To Mr. Thwaites). The greater part of those 168,033,115 tons of sewage would be discharged on the 20,000 acres of sands, would they not?—I believe they did intend to discharge there.

107. If they did you would allow, would you not, that it would be nearly seven feet deep if it were all collected there at once?—No doubt.

223. (To Mr. Thwaites). Are you aware that Messrs. Hofmann and Witt have stated that the liquid contains six-sevenths of the sewage in solution, and that there is only one-seventh in the mud?—I believe that that is so.

356. (To the same). Are you aware that Messrs. Hofmann and Witt have stated, and that those who made this report have corroborated them in that statement, that 1250 tons of liquid sewage are equal in value to one ton of guano?—Yes.

380. (To Mr. Bazalgette). When would you put the sewage over the land between the Abbey Mills and the Maplin sands, during the whole of the year?—I can hardly conceive that the sewage would be applicable to the land during the whole of the year.

381. (To the same). What would you do with it at those times at which it was not applicable to the land?—I should take it into the present outfall.

509. (To Mr. Hemans). I suppose you are aware that in eight hours out of the 24 the half of the sewage flows?—I am aware that there is a larger proportion at one period of the 24 hours than there is at another.

512. (To the same). Then if the half of it flows in eight hours, that would be 250 cubic feet per acre in eight hours?—Supposing the half to come in eight hours it would be 250 cubic feet.

513. (To Mr. Hope). What would be the thickness of this per acre per annum?—It comes to seven feet per acre per annum.

514. (To Mr. Hemans). Do you confirm that?—On 12,000 acres only it would be seven feet thick, but on 20,000 acres it is four feet per acre per annum.

757. (To Mr. Hope). You have stated that the Edinburgh experiments were a great success?—Yes.

758. (To the same). To whom have these experiments been a great success?—To the proprietors.

759. (To the same). They have not been a great success to the ratepayers?—Certainly not; they get no benefit whatever from the arrangement.

762. (To the same). But with regard to the value of the sewage to the town of Edinburgh, do they receive anything for it?—Nothing; the sewage flows into a natural stream, which happens to pass through this farm; and passing through the farm they have gradually adopted it for irrigation, and extended the system, as they found it paid better than ordinary cultivation.

763. (To the same). How many tons of sewage do you propose to distribute on the Maplin Sands?—If the whole of the sewage is placed there, it would be about 6000 tons per acre per annum.

825. (To Mr. Hope). It has been stated that the value of the sewage has been computed at 6s. per head of the population; upon what estimate is that calculation based?—I believe that that is based upon a very long series of experiments by a number of different chemists, but that is only the theoretical value.

826. Has any reference to the expense of carrying the sewage from the place at which it is thrown into the river to the place of its application?—None whatever.

(Report of the Main Drainage Committee for 1864, vol. 487).

PATENTS.

ABRIDGMENTS OF PROVISIONAL AND COMPLETE SPECIFICATIONS.

Improvements in the manufacture of white-lead, and in the purification of carbonic acid gas used in the said manufacture, and in apparatus therefor. George Haseltine, Southampton Buildings, London. (A communication from Ass. P. Meylert, New Britain, Connecticut, U.S.A.). January 18, 1873.—No. 213. My invention relates to an improved apparatus for manufacturing white-lead, and also to improved methods of purifying the carbonic acid gas used in the said manufacture. I use an apparatus whereby the carbonic acid gas required for corroding the lead is used to assist in conveying the vapour of acetic acid into contact with the metallic lead, and is also used to assist in vapourising the acetic acid required for corrosion. The method of manufacturing white-lead by the said apparatus is as follows:—Thin strips or pieces of lead of any convenient size are placed in a suitable chamber or house. At any convenient distance from this chamber and connected thereto by a pipe or pipes, or within the chamber itself, is placed a vessel, reservoir, or receptacle of any suitable form or shape containing acetic acid of any suitable strength; carbonic acid gas, either pure or mixed with oxygen or with common air, is forced through a suitable pipe or pipes into the said receptacle containing acetic acid, the gas being passed through or over the acid and then passed from the said receptacle freely into the room containing metallic lead for corrosion; steam is likewise introduced at any convenient point and mingled with the gas and vapour.

An improved process and apparatus for extracting and recovering oils, fats, and similar substances. John Cox, analytical chemist, Newcastle-on-Tyne, and Samuel Cox, hydraulic engineer, Hatcham Road, Surrey. January 18, 1873.—No. 214. Our said invention relates to the extraction and recovery of oils, fats, spermaceti, paraffin, wax, and other like substances by the action of a volatile solvent passed by distillation through materials containing these oily, fatty, or other substances, the said volatile solvent being recovered after each operation.

A process for forming carbonic oxide from oxyhydrogen vapour or steam, and an apparatus for utilising the same for heating purposes. Levi Stevens, San Francisco, California. January 18, 1873.—No. 216. This invention consists in the discovery of the conditions by which carbonic oxide or protoxide of carbon is formed from oxyhydrogen vapours or steam. Also in distilling bituminous coal, asphaltum, pine-wood, and in fact any substance that will distil a carbon or hydrocarbon vapour or gas, which vapour or gas is used in the disintegration of oxyhydrogen vapour or steam. The invention further consists in the application of carbonic acid or protoxide thus formed to steam-boilers, furnaces, and all places where heat is required, this being effected by the use of any suitable number of retorts, which are set so as to be heated by the same furnaces which serve for the steam-boilers. These retorts are charged with any suitable or convenient substance which will produce a carbon or hydrocarbon vapour by distillation and at the proper time. Superheated steam (from an apparatus also heated by the furnaces) is let in at a temperature at which the carbon is decomposed. Protoxide of carbon and free hydrogen are thus evolved, and the gases thus produced are led by suitable pipes into the furnaces.

Provision is also made for the introduction of oxygen from the air for the complete combustion of the gases thus introduced.

Improvements in stoppering bottles for aerated or gaseous liquids. Charles Farrow, mechanical engineer, Great Tower Street, London. January 18, 1873.—No. 218. This improved stopper is formed by attaching to the ordinary bottle a tube of flexible or elastic material, such as india-rubber, or india-rubber lined with linen, one end of this tube being passed over and attached to the neck of the bottle by string or wire. To close the bottle, the upper part of the tube may be either doubled down and tied, or strangled.

An improvement in pediment or cistern barometers, and in the means of filling the same. Christopher George, Staff-Commander R.N., Herne Hill, Surrey, and Henry Porter, optician, Strand, Middlesex. January 18, 1873.—No. 224. The cistern is made open at bottom, so that when fitted on the mouth of the tube, and the two inverted, the mercury may be poured into the tube without the use of a funnel, a twisted or spiral cord having been first introduced into the tube. This cord has a brush or feather at its extremity, which reaches the closed end of the tube, and the mercury on being poured in is broken up into globules, which pass down between the cord and the sides of the tube. The cord is then rotated in the tube, which raises it out of the mercury bringing with it all air-bubbles. When the tube is filled, the cistern is closed by a vulcanised india-rubber stopper, and the instrument brought to its proper position.

A new or improved charcoal to be used for purifying sewage and other foul waters, and for disinfecting and deodorising purposes. James Robey, sugar refiner, Manchester. January 20, 1873.—No. 230. The features of novelty in this invention consist in drying and charring the sludge or precipitant obtained by treating sewage after the manner of the Native Guano Company, Limited, when practising according to either of the two patents granted to Messieurs Sillar and Wigner, bearing date June 15, 1868, No. 1954, and to W. Wigner, bearing date May 12, 1870, No. 1354, in both of which patents clay is the principal precipitant, or the sludge or precipitant obtained by treating sewage by other precipitating processes in which clay is used, and so producing a charcoal which is useful for the various purposes described; or a similar charcoal is produced by mixing clay with the refuse carbonaceous matter from prussiate of potash manufactories, and then charring the mixture.

An improved press for obtaining salt of tin and other products from waste or refuse tin-plate. Adolf Gutensohn, analytical chemist, Gresham House, London. January 22, 1873.—No. 258. I use a vessel made of any material not affected by the action of acids. In this vessel I place the tin-plate or refuse, with muriatic acid until it has acquired a dull grey colour; the acid is then poured off into a second vessel containing the same weight of tin-plate waste; here it again remains till the colour of the waste is dull grey; after which the same process is repeated in a third vessel. Ammoniac is added until, on testing with a solution of extract of indigo, a blue-black deposit is formed. A further quantity of the solution of extract of indigo is then added until the deposit ceases to be formed. The solution is then allowed to boil for a few minutes, and then filtered. This solution is then evaporated, and the salt allowed to crystallise. Metallic tin is obtained from the purified salt of tin by means of zinc.

Improvements in the manufacture of incombustible paper, in ink for writing on the same, and in covers and envelopes for the said paper or other paper when made into books or packages. George William Halfpenny, 25, Lower Shadwell, Middlesex. January 23, 1873.—No. 262. The chief features of novelty in this invention are—First. The making of a paper which shall be ordinarily incombustible under such circumstances as fires occurring in dwelling-houses, factories, and other buildings. The paper is composed chiefly of the following ingredients, viz., linen or vegetable fibre and asbestos with borax and alum, to which is sometimes added a small quantity of ground or powdered glass and of common salt. Secondly. An ink for writing on the above paper made from the mineral or metallic earths. Thirdly. Incombustible covers or envelopes for books and packages made from the incombustible pulp or paper with or without sheets of talc or sheets of talc with or without the incombustible paper.

Improvements in treating sewage for the purpose of making manure and purifying sewage. Frederick Jacobsen, Redfern House, Edinburgh. January 23, 1873.—No. 266. Mixing phosphate of lime along with diluted sulphuric acid, which sulphuric acid is so diluted with sewage instead of with clean water, whereby a superphosphate is produced, which is then mixed with the more solid sewage deposit obtained by any of the known methods for producing subsidence and decantation.

TO CORRESPONDENTS.

* The STUDENTS' NUMBER of the CHEMICAL NEWS will be published on Friday, September 12th. Gentlemen holding official positions in the Universities, Medical Schools, &c., of the United Kingdom, where Chemistry and Physical Science form a part of the Education, who have not yet forwarded the necessary information to our office for publication in that number, will confer a favour by sending it with the least possible delay.

* Vol. XXVII. of the CHEMICAL NEWS, containing a copious index, is now ready, price 11s. 4d., by post, 12s., handsomely bound in cloth, gold lettered. The cases for binding may be obtained at our office, price 1s. 6d. Subscribers may have their copies bound for 2s. 6d. if sent to our office, or, if accompanied by a cloth case, for 3s. Subscribers wishing to complete their sets of volumes are requested to apply to the publisher, who will give them information respecting scarce numbers and volumes. Vol. xxviii. commenced on July 4th, and will be complete in twenty-six numbers. *READING CASES*, price 1s. 6d. each, post free, may also be obtained at the Office.

SUPPLEMENT TO THE CHEMICAL NEWS.

VOL. XXVIII. No. 719.

ESTIMATION OF HYDROSULPHURIC ACID IN MINERAL WATERS.

By W. J. LAND.

In an apartment free from direct sunlight, preferably a room lighted by non-actinic rays, prepare a moist precipitate of pure carbonate of silver, by dissolving 8.5 grms. of pure nitrate of silver in one-fourth of a litre of distilled water; also, 2.7 grms. of chem. pure dry carbonate of soda in an equal volume of distilled water previously heated to about 180° F. Mix the solutions (gradually), simultaneously stirring the mixed solutions with a glass rod. Allow the precipitate to subside, decant the supernatant liquid with a pipette or small syphon, wash with hot distilled water, decanting and washing successively five or six times to obtain a comparatively clean precipitate of carbonate of silver, in which substance we have a most excellent reagent for removing every trace of hydrosulphuric acid, small quantities of alkaline sulphides and haloids, from their solution in water. Add, to a definite quantity of the water to be operated upon (say 1 litre if strongly impregnated, and 10 litres if weakly impregnated with gas), the still moist precipitate or *magma* of carb. of silver, until the precipitate, at first black in colour, becomes brown or greyish-brown, thus indicating an excess (as desired), of the silver salt. Shake or stir well, warm gently, and allow the precipitate to subside perfectly. Decant the greater part of the liquid, transfer the remainder of the liquid with every trace of the precipitate to a small beaker, and digest the latter with pure dilute nitric acid (1 of acid to about 4 of water), thus removing the excess of carbonate of silver. Decant and wash well with distilled water. Transfer to a weighed filter, wash with a moderately dilute solution of hydrate of ammonia (to remove silver haloids), testing the ammoniacal filtrate occasionally with sulphide of ammonium, or other suitable reagent, to discover the presence or absence of the silver haloids in the washings; when all traces of these have disappeared, wash well with distilled water; lastly, with pure 95 per cent alcohol, dry on a water-bath. Remove the dried sulphide of silver from the filter, ignite the latter in a small porcelain crucible with a grain or two of sulphur; heating to incipient redness (to expel excess of sulphur), add the ignited product to the larger quantity of the precipitate, transfer to a desiccator, afterwards weigh. 124 of the sulphide corresponds to 17 of hydrosulphuric acid sought.—*American Chemist.*

NOTICES OF BOOKS.

The Chemistry of Sulphuric Acid Manufacture. By H. A. SMITH. London: E. and F. N. Spon.

THAT sulphuric acid plays in chemical manufactures a part analogous to that sustained by iron in the mechanical arts is not to be disputed. Such being the case it is surprising that every point connected with its production has not been thoroughly studied both from a theoretical and practical point of view. Yet the author of this useful little work says no more than the truth when he declares

that:—"The interior of the lead chamber is comparatively an unknown land to us." Mr. Smith, in the brief compass of 81 pages, has made a very praiseworthy attempt to supply this deficiency in our knowledge, and we hope that he may find time and opportunities to carry out and complete what he has so well begun.

The first part of the work is devoted to a consideration of the presence of arsenic in the sulphur ores commonly employed. The amount of this serious impurity he finds to be greater than is generally stated in standard works, ranging from 0.943 per cent in Belgian pyrites to 1.878 in Westphalia. The author's determinations certainly accord much better with the amount of arsenious acid present in commercial sulphuric acid, hydrochloric acid, salt-cake, and other products and residues implicated than do the analyses given in Richardson and Watts's "Chemical Technology." In that important work the highest mean percentage of arsenic is described as ranging from 0.31 to 0.33, whilst some pyrites are described as containing mere traces, and others as perfectly pure, "results which," our author remarks, "are never corroborated when these ores are being worked on a manufacturing scale." The means for preventing the escape of arsenious acid into the atmosphere, and of removing it from sulphuric acid, are carefully investigated. The preference is given to the use of sulphuretted hydrogen, though the mode of its application is still an open question.

We next come to an "experimental examination of the circumstances which determine the action, *inter se*, of the gases in the lead chamber." The author, founding on careful experiments, controverts the common view that no action can take place between oxygen and sulphurous acid gases without the intervention of water, either in the liquid or gaseous state. He finds, on the contrary, that "action does take place between the dry gases under certain circumstances." He draws here the general practical rule that, "the higher the temperature the more steam is required."

In successive sections we find experimental investigations into the distribution of gases in the lead chambers, the temperature at which nitric acid acts upon sulphuric acid, the distribution of heat in the chambers, and an inquiry into the best form of chamber. We quote the following as his practical conclusions:—

1. The best form of chamber is one which is long and not high, of somewhat the following dimensions:—Length 150 feet, width 25 to 30 feet, height 10 or 12 feet.
2. The temperature of the chamber should be kept as nearly as possible about 200° F.; this fact also acting as a regulator for the amount of steam thrown into the chamber.
3. That in "starting" a chamber sulphuric acid should be run on the bottom in preference to water as at present generally employed."

In a final section on the Gay-Lussac tower and the escape of sulphurous acid to the atmosphere, he condemns the tower on the following just principle:—"Instead of a careful inquiry into the cause of the escape of nitric oxide, we take it as a recognised fact that such a gas must escape, and that our only hope rests in some method of absorbing it. Referring to the present escape of sulphurous acid from alkali works, the author recommends a prohibitory law similar to the Alkali Act. Whilst fully admitting both the nuisance and the waste thus occasioned, we cannot help asking what proportion does the sulphurous acid escaping from chemical works bear to that evolved from the pyrites present in coal? Our conviction is, that in any district where the highly sulphurous Lancashire coal is used the former is a mere "drop in the bucket."

We strongly recommend this treatise to all of our readers who are interested in the manufacture of sulphuric acid, and we hope that its practical, experimental spirit may be reproduced by writers on other departments of chemical technology.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Under this heading will be found an encyclopedic list of chemical papers published abroad during the past week, with abstracts of all susceptible of advantageous abridgment. The two half-yearly volumes of the CHEMICAL NEWS, with their copious indices, will, therefore, be equivalent to an English edition of the "Jahresberichte."

NOTE. All degrees of temperature are Centigrade, unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances de l'Académie des Sciences, August 11, 1873.

On Cyanides.—M. Berthelot.—A continuation of the thermo-chemical investigations with which the author has been occupied for some time. The author mentions as an important instance of an "inverse displacement" that hydrocyanic acid displaces hydrochloric acid from combination with the oxide of mercury. On the other hand, concentrated hydrochloric acid, and even hydrochloric gas, expel immediately, and at ordinary temperatures hydrocyanic acid from cyanide of mercury; and dilute aqueous hydrochloric acid completely decomposes cyanide of potassium in solution. These facts, he contends, are in perfect accord with his theory.

Re-solution of Precipitates.—M. Berthelot.—The theory of Berthollet as given in his "Statique Chimique" is that if we treat a dissolved salt with an acid capable of forming an insoluble salt with its base the latter is generated in consequence of the partition of the base between the two acids, and is then precipitated in virtue of its insolubility. The separation of this body having withdrawn it from the field of chemical action, a fresh partition of the base takes place between the two acids in the liquid, and consequently a fresh precipitation. This is still the admitted law of the science. The thermic theory, on the other hand, reproduces the notion of an elective affinity; the work done by which is measured by the heat liberated in the reactions of the bodies taken in comparable states. If the bodies were isolated from every solvent, and if each acid formed with the base only one single compound, there would be no partition—contrary to the opinion of Berthollet—and, in consequence, insolubility would not play any part in chemical statics. It would be the same in the presence of water if none of the compounds formed in its absence did not undergo decomposition on its part. But there are acids capable of forming several compounds with one and the same base. Further, water decomposes in part according to its mass, and to the relative proportions of acid and of base, the acid and the basic salts, the ammoniacal and the metallic salts, &c. These circumstances determine intermediate equilibria; that is to say, a varying partition of the base between the two acids. In solutions, and for soluble salts, the reality of this partition can be established by thermic evidence (*Comptes Rendus*, tome lxxv., p. 435, 480, 508, 583; tome lxxvi., p. 94); or by the method of two solvents (*Annales de Chimie et de Physique*, 4 series, tome xxvi., p. 433). To decide between these theories we must seek cases where they lead to conflicting results, such as those where each of the two antagonistic acids forms only a single basic compound stable in presence of water. The proof is realised by mixing acetate of silver and dilute nitric acid, when the insoluble acetate is immediately changed into dissolved nitrate. It would be easy to multiply analogous examples of the complete displacement of a monobasic acid in an insoluble salt by a single equivalent of another monobasic acid which forms an insoluble salt. The decomposition of insoluble carbonates by monobasic acids, such as the hydrochloric and nitric, in liquids either concentrated or so dilute that the carbonic acid may remain dissolved, is equally total. In dilute solutions it gives rise some-

times to a liberation of heat, sometimes to an absorption (carbonate of silver and nitric acid). The decomposition of the insoluble carbonates falls under the foregoing theory. Such results may serve as a criterium between the theory of Berthollet and the new thermic theory.

Methods of Analysing the Natural Phosphates employed in Agriculture.—M. C. Mène.—The author has already called attention to the analysis of phosphates by the "ammonia" and the "citric acid" (or acetic) methods, and to the erroneous results to which these methods may lead (*Comptes Rendus* tome lxxvi., p. 1410). He now produces results of analyses made in his laboratory which confirm what he formerly announced. Coprolites from the Department Nord, found to contain 45 per cent of tricalcic phosphate by the citric acid and ammonia phosphate of magnesia process, gave only traces of phosphoric acid by the "bismuth process." Other phosphates from the Rhone giving 53 per cent of phosphate by the citric method, did not yield even a trace of phosphoric acid by the bismuth process. If an attempt was made to check the results obtained by the former method by re-dissolving the precipitate, and trying to produce other reactions no phosphoric acid could be found. On the contrary, it appeared that this precipitate was silica and alumina. If any one goes over the details of the process he will see that the ammoniacal liquor which serves to precipitate the ammonia phosphate of magnesia, throws down also alumina and silica, and that in the absence of phosphoric acid these two bases (?) may simulate its presence. The author, however, does not attack the citric acid method in cases where silica and alumina are absent, having frequently obtained by its means with the phosphates of the Antilles, and of Limburg, with bones, &c., results quite comparable to those given by the bismuth process. He considers that bismuth precipitates phosphoric acid so quickly and certainly that no other reagent can be compared with it. In many determinations he has never found a deviation of more than 0.25 per cent, which is commercially inappreciable.

On Fluoren.—M. Barbier.—Fluoren, a new and highly fluorescent carbide, is contained in the parts of coal-tar which are volatile between 300° and 340°; its formula is $C_{26}H_{10}$. On treatment with chlorine it forms a bibromic derivative, $C_{26}H_8Br_2$, fusible at 166° to 167°, and crystallising in splendid tables belonging to the clinorhombic system.

Corindon of North Carolina, Georgia, and Montana.—Lawrence Smith.—Specimens of this mineral have been found in crystals of a pyramidal form. They vary greatly in colour, being grey, green, rose, blue, red, with all intermediate shades. Diaspore, so abundantly associated with corindon at Chester (Massachusetts), has not been found accompanying it here. Specimens supposed to be diaspore were colourless kyanite. Chlorite envelopes and penetrates the corindon. Its composition is—

	Large Plates.	Friable.
Silica	27.00	29.15
Alumina	21.60	10.50
Oxide of iron ..	16.63	23.50
Magnesia	22.00	25.44
Water	12.30	10.04

Margarite (emerylite) accompanies corindon or emery everywhere; in the present localities it is abundant. Its composition is:—

Silica	32.41
Alumina	51.31
Lime	10.98
Soda	2.43
Water	2.13

Zoisite.—This mineral appears in two forms; a black and a transparent green variety. Both of these have been called *Arfvedsonite*, but neither has the composition of that mineral. The following is the composition of three kinds:—

	Transparent Green.	From Geneva.	Black Variety.
Silica	45°70	43°59	45°90
Alumina	24°01	27°72	13°34
Peroxide of iron	4°56	2°61	11°46
Lime	13°34	21°00	12°20
Magnesia	8°03	2°40	12°53
Soda	2°91	3°08	3°39
Water	0°60	—	0°66
Chromic oxide	0°52	—	—

Andesite.—This mineral is found in a granular form. Its composition is—

Silica	64°12
Alumina	24°20
Soda	9°28
Lime	2°80
Oxide of iron	0°14

Action of Platinum and Palladium on the Hydrocarbides.—J. J. Coquillion.—It is known that a spiral platinum wire, previously heated to redness and placed in contact with vapours of alcohol or ether, gives rise to a variety of products, of which the chief are aldehyd and acetic acid. All the mono-atomic alcohols and their ethers act in an analogous manner, producing the aldehyd and the acid corresponding to the alcohol. All the hydrocarbons, the volatile oils, anilin, &c., maintain the incandescence of the platinum spiral. The fixed oils, the sulphuretted oils, such as those of garlic and mustard, seem to form an exception. The author has collected the products of combustion in the case of three substances belonging to three different series—toluen, $C_{11}H_8$, of the series $C_{2n}H_{2n-6}$; formen, C_2H_4 , of the series $C_{2n}H_{2n+2}$; and ethylen, C_2H_4 , of the series $C_{2n}H_{2n}$. Toluene gives up 2 equivalents of hydrogen to form water with the oxygen, and yields aldehyd and benzoic acid. Formen yields formic acid, and ethylen produces acetic acid. The action of palladium is more powerful than that of platinum. It becomes wrinkled on its surface, and breaks easily after having been in use for some days; moreover, it loses weight very distinctly.

Reply to Recent Objections of M. Tacchini (Solar Physics).—M. Faye.—First, as to penumbrae. M. Faye's theory is that they are due to a lowering of temperature about the solar vortices. The photosphere somewhat altered is continued to a certain depth in the form of a sheath round the vortices. When by some accident, as sudden increase of intensity, or extended rotation, these conical walls are reached they may take for a time a well-marked vertical movement; but in general they have only a slight hardly perceptible rotation. Hence it is not surprising that in the first five months of the present year, M. Tacchini observed only six cases of vortical structure. Again, M. Tacchini supposes M. Faye's theory requires a symmetry in the mode of rise of the hydrogen in the spots, and that there should always be a well-formed corona of protuberances. M. Faye rejects this idea; the sun's structure, and the analogy of terrestrial cyclones are both against it. M. Faye is represented, thirdly, as holding that there are never protuberances without spots. He quotes various passages from his writings contradicting this.

Direct Demonstration of the Fundamental Principles of Thermo-Dynamics.—Continued extract from memoir by M. Ledieu.—It treats of quantities which characterise—(1) The absolute temperature of a body; (2) its physical and constitutive state.

Detailed Geological Map of France.—M. Elie de Beaumont.

Note on the Public Works of the United States of America.—M. Belgrand.—The author notices some points (referring to bridges, water-works, railways), in the report of M. Malezieux, a French engineer sent over by the Government in 1870.

Propagation of the Tide at Different Points on the French Coast.—M. L. Gaussin.—(Extract from memoir.)

—The author examines the tidal phenomena in about a dozen French harbours and four English. As to ocean ports (Cordouan, Saint Nazaire, Port Louis, &c.) the tide is propagated more slowly in still than in current water. In the Channel, on the contrary, except at Havre, the tide arrives more quickly in still water on both coasts. Further North on the German Ocean, at Calais, and at Dunkirk the former *regime* recurs. The author gives the average variations of retardation in the daily tides, the syzyz tidal being taken as normal type. Comparing the curve for Havre with that for the neighbouring port of Fecamp, the minimum for the former and maximum for the latter takes at syzyzies; the Havre minimum, + 34 m.; corresponds to the Brest tide of 11h. 30m.; the Fecamp minimum, - 23m., corresponds to the tide of 11h. The difference of variations of retardation in the propagation of the tide in the two ports is thus, in relation to the tide in current water, 57m. in still water. Formerly, before certain embankments were constructed in the Seine, it was only 33m. There is, besides, an absolute change at Havre. In current water the full sea reaches Havre 36m. more quickly than before. These changes are attributed to considerable diminution in the beaches of the Seine estuary, which have exerted a retardative action, and do still, though in less degree.

Passage of Gases through Colloidal Membranes of Vegetable Origin.—M. A. Barthelemy.—The author repeated the experiments which Graham made with caoutchouc, with leaves of certain varieties of *Begoniaceae*. Though it was difficult to preserve in the several experiments the same conditions of external pressure, temperature, and hygrometric state, the numbers sufficiently show that oxygen passes more quickly than nitrogen, and that air thus dialysed contains, on an average, 36 per cent oxygen (a number slightly under that which Graham obtained with caoutchouc). In another experiment, having made CO_2 pass over the membrane, he marked the point to which mercury descended in an hour; then passing nitrogen or oxygen, he marked how long the mercury took to descend to the same level. The results closely agreed with Graham's; and warrant the conclusion that the natural colloidal surfaces of plants have for CO_2 an admittance power 13 to 15 times greater than that for nitrogen, and 6 to 7 times greater than that for oxygen. Carbonic anhydride passes less quickly than hydrated carbonic acid. The author remarks that "cuticular respiration appears sufficiently proved by the presence of colloidal membrane in all organs; by the similarity (physical and chemical) between this membrane and caoutchouc; by Graham's experiments; by measurements of the passage of gas through colloidal membrane; and last by M. Boussingault's experiments, which attribute to the upper surface of leaves, devoid of stomates, a decomposing power greater than that of the under face covered with these small orifices."

Variations of Hæmoglobin in Disease.—M. Quinquaud.—In a healthy person the proportion of hæmoglobin is about 125 to 130 grs. per 1000 grs. of blood. But it varies very much in disease; sometimes, as in cancer, falling as low as 38 grs. It may thus serve, M. Quinquaud thinks, in diagnosis and prognosis. He gives several instances, and adds a determination of the hæmoglobin for some twenty different kinds of disease. Cancer, chlorosis, and tubercular phthisis of the third degree, are those which diminish the proportion most.

No. 9, August 30.

Meeting of the French Association for the Advancement of Science at Lyons.—(Chemical Section).—Session of August 22.—M. Gautier described a new derivative of glucose, $C_{12}H_{22}O_{11}$, obtained by the action

of hydrochloric acid. The glucose is dissolved in alcohol at 95 per cent, and the solution saturated with hydrochloric acid, keeping the temperature at 0°. The mixture, after having been kept cold for twenty-four hours, is evaporated over lime in a vacuum, when there remains a syrup which is purified by washings in ether, treatment with baryta, and successive solutions and evaporations in absolute alcohol. The compound is a white, crystalline, solid, deliquescent mass, without taste, incapable of fermentation, reducing cupro-potassic liquid, and not capable of becoming hydrated below 160°, when it is converted into a body differing from glucose. This compound, resulting from the union of two molecules of glucose with the elimination of a molecule of water, does not appear to be an ether of glucose viewed as an alcohol, but as a body like aldol, analogous to the products yielded by the aldehyds. M. Gautier proposes to give it the name glycaldan.

With reference to this paper M. Wurtz explained the constitutional formulæ of glucose, which explains its double function as a pentatomic alcohol and as an aldehyd.

E. Grimaux stated that Musculus had obtained by the action of sulphuric acid upon glucose a body which appeared to be dextrin; resulting from the union of two molecules of glucose, performing the functions of an alcohol, with separation of a molecule of water.

Ch. Girard presented to the section specimens of certain coal-tar colours, such as rosanaphthylamin, safranin, Paris violet, &c., and described the method of their preparation.

M. Carnot described a deposit of bismuth which is worked at present at Corrèze. It consists of metallic bismuth, oxide, and sulphide. The oxide is the most abundant ore, and contains 70 per cent of bismuth. The process of extraction consists in exhaustion with hydrochloric acid, and precipitation by means of iron. The bismuth then undergoes the ordinary treatment for the removal of lead and arsenic. The stratum contains also molybdate of lead, tungstate of lime, and mispickel.

M. Friedel has examined two samples of rich tellurium ores from Asia Minor. The ore is a telluride of gold and silver, containing 21 per cent of gold, and 37 per cent of silver. The other is a telluride of lead.

M. Grimaux described the action of bromine upon dimethylbenzin or xylene, $C_6H_4(C_6H_5)_2$, at the temperature of 140°. He showed that whilst forming a bibromated derivative, the bromine substitutes itself in the two groups CH_3 , yielding a dihydrobromic ether of glycol. The author announced that he had observed the same reaction with ethylbenzin, $C_6H_5-CH_2-CH_3$, which yields a derivative, $C_6H_5-CHBr-CH_2Br$, identical with the bromide of cinnamen. This bromide, on boiling with water, loses all its bromine in the state of hydrobromic acid, and forms a very soluble crystalline body, probably cinnamonic glycol. The same procedure, applied to trimethylbenzin or to ethylmethylbenzin, would doubtless lead to the formation of a tribromhydrin of an aromatic glycerin, but the author has had recourse to another reaction for the production of the latter.

Cinnamic alcohol or styron, $C_9H_{10}O$, may be considered as phenylallylic alcohol. Like allylic alcohol it fixes 2 atoms of bromine, and yields a crystalline dibromhydrin, $C_9H_{10}Br_2O$. Grimaux has also obtained tribromhydrin, aceto-dibromhydrin, and chloro-dibromhydrin, all crystalline. Triacetin is a syrup-like liquid. The glycerin, $C_9H_{12}O_3$, obtained by the action of water upon dibromhydrin is a soft transparent gummy substance of a bitter taste, very soluble in water, and which behaves with formic acid similar to the polyatomic alcohols, setting free carbonic acid. The author gives to this glycerin the name of stycerin.

These numbers contain nothing of interest to our readers.

Bulletin de la Société d'Encouragement pour l'Industrie Nationale, No. 249, September, 1873.

Report given in by M. Salvétat for the Committee of the Chemical Arts on a New Form of Muffle for Burning Designs on Porcelain, Earthenware, Glass, and Crystal.—M. Pollard, at Auteuil.—This paper would not be intelligible without the accompanying diagrams.

Report Given in by Hervé Mangon for the Committee of Agriculture on the Procedures of Preparing Animal Matters Designed for the Manufacture of Manures.—M. Coignet.—Horns, hoofs, hair, refuse of tanned hides, and woollen rags are very rich in nitrogen and other fertilising ingredients; but the difficulty of reducing these matters to a fine powder so as to mix with the soil, and the extreme slowness of their decomposition in the ground, prevent them from giving a profit in proportion to the value of their constituents. M. Coignet seeks to overcome these difficulties as follows:—Leather waste of all sorts, horn, and analogous matters are introduced into a stove of about 20 cubic metres in capacity. This stove is of sheet-iron. It has at its upper part a door for charging, and a side door below for emptying. A floor of bricks is formed at some decimetres above the bottom of the stove. The lower part of the stoves communicates, by means of a large sheet-iron pipe, with the chimney of the works, or with an aspirating ventilator. By the side of the stove is a rectangular furnace in which coke is burnt, the chimney of which opens into the upper part of the stove above-mentioned. The hot air and the products of combustion traverse the contents of the stove from the top to the bottom. When the stove is filled, and its doors are closed and luted, the furnace is kindled, and the doors placed above the fire are opened so that a large volume of air may enter the stove at a temperature not exceeding 150°. When the whole mass of the stove has reached this temperature the furnace is well charged with coke, and its doors are closed so as merely to admit air sufficient to prevent it from being extinguished. At the same time a current of steam is allowed to enter the chimney (leading from the furnace to the stove). This steam mixes with the products of combustion, and traverses thus the stove at a temperature of 150° to 160°. After some hours of this treatment the horn, leather, &c., is found slightly swelled, and quite dry and friable, without having lost any nitrogen. The mass is allowed to cool, withdrawn from the stove, powdered under edge-stones and sifted.

On Blast-Furnaces.—M. L. Gruner, Inspector-General of Mines.—A long and important paper, with several illustrations, and not suited for abstraction.

THE CHEMICAL NEWS.

Vol. XXVIII. No. 720.

(STUDENTS' NUMBER.)

SCIENCE IN THE UNIVERSITIES.

THE Third Report of the Commission on Scientific Instruction and the Advancement of Science relates exclusively to the Universities of Oxford and Cambridge. The Commissioners at the outset of their report draw a necessary distinction between Science as limited by the scope of the duties assigned them, and "the mental and moral sciences, as well as those parts of human knowledge and culture which are not usually regarded as having any scientific character."

The report is too voluminous, and the subjects to which it relates are too important, to permit of our dealing with all the matters considered in it. We select, therefore, those which, in our opinion, are of primary importance.

It will not surprise those who have seen the previous reports of the Commission to hear, that, in considering what may be regarded as the connecting link between school and college careers, the Commissioners expressing a preference for an examination at leaving school to college matriculation examinations, insist strongly on the importance, for the future, of scientific education in England; that, in case such an examination should be instituted, those parts of science which are suitable for the education of boys should be recognised in it. Passing thence to the question of the university curriculum, they present the arguments for and against the desirability of insisting on a certain amount of literary culture in the case of scientific students. The Commissioners, while expressing their opinion that some evidence of literary culture should be required by the University from every student, urge that the principle should be extended, and that, "in like manner, evidence of corresponding scientific culture should be required from the student of classical literature or of theology." It is urged, however, that the student of any special department should be freed at an early period of his university career from any obligatory subjects of study.

Passing over the suggestion that scholarships should be founded in natural science, we come to an extremely important part of the report—the discussion, namely, of the existing arrangements for science teaching at the two universities. We notice, with strong approval, that, in passing, the Commissioners draw attention to the possible mischief resulting from the influence of the competitive mathematical examination at Cambridge. "It does not seem probable," they justly notice, "considering the keenness of the competition for high places in the mathematical tripos, that students would be willing to interrupt their more direct preparation for examination by attending numerous courses of professors' lectures." The Commissioners evidence also the existing state of the scientific institutions at the two universities, and although they do not

express absolute dissatisfaction, they indicate their opinion that our universities fall short of the standard of excellence attained elsewhere.

But perhaps the most noteworthy, as it is certainly the most critical (we do not say questionable) proposition in the whole report, is contained in the following paragraph:—

"It is, in our opinion, most important that a certain number of fellowships should be appropriated to the direct promotion of learning and research in various directions. It has been objected to this proposal that the fellowship system, as hitherto administered, has not shown any great tendency to encourage original research, either in the field of learning or in that of science; that when an office is created simply and solely with the view of giving a man leisure for original research, there is always the appearance, to say the least, of creating a sinecure; and that it is impossible, as Professor Jowett has said, to get a man for money who can make a discovery. But, though you cannot get a man for money to make a discovery, you may enable a man who has shown a special capacity for research to exert his powers; and we are of opinion that, unless an effort is made to do this, one of the great purposes for which learned bodies, such as the colleges, exist, may run the risk of being wholly lost sight of." The Commissioners do not state what this purpose is, nor are we aware of any purpose, legitimately included in the general object for which colleges have been founded, which can be said to call for the foundation of research fellowships. It may be highly desirable that such fellowships should be established, and convenient that a portion of the wealth of our colleges should be applied to the promotion of original research; but it can scarcely be said that, when the colleges were first established, any such purpose was in view. "Scientific discoveries," proceed the Commissioners, "rarely bring any direct profit to their authors, nor is it desirable that original investigation should be undertaken with a view to immediate pecuniary results. 'Research,' as Lord Salisbury has observed 'is unremunerative; it is highly desirable for the community that it should be pursued; and therefore the community must be content that funds should be set aside to be given, without any immediate and calculable return in work, to those by whom the research is to be pursued.' It may be that properly qualified candidates for such scientific offices would not at first be numerous, but we believe that, eventually, a considerable number of fellowships might be advantageously devoted to the encouragement of original research."

We must confess to some feeling of anxiety as to these suggestions. As an abstract proposition, it appears reasonable enough to assert that scientific workers should be helped in the manner indicated. But certain recent events have made it but too manifest that, so soon as a scheme for such a purpose comes to be definitely propounded, the men who will show in front among the claimants for this species of assistance will not be the really earnest workers in science, but the scientific Micawbers, who work at science under the continual hope that "something will turn up" for their own special advantage. Proposals savouring of self-interest have already shown what might be expected if ever any wide scheme for the appropriation of college funds to scientific research were set on foot. Any

mischievous wrought in this way, any circumstance by which the name of science would be brought into contempt, would be almost irreparable, especially as occurring just at the outset of the new arrangements by which it is hoped that, ere long, the real interests of science will be notably advanced.

With this exception, the report before us is, in our judgment, eminently satisfactory. There can be no question that the relations of our universities to science are at present not all that could be desired, and that they admit of ready improvement. The suggestions offered to this end by the Commissioners are reasonable and moderate; there is nothing in them to offend what may be called university susceptibilities, although they are not all such as the thorough going university man would accept. The mere fact, however, that not a few among the suggested alterations have come from and have had the support of men high in position in our universities, shows that the interests of these bodies have not been lightly regarded. We have very little doubt that good results will follow from the labours of the Commissioners; and if we have found reason to criticise one feature of their report, it is only because we would desire to see removed all risk that jobbery might one day become an element in the election to university fellowships, and that thus the interests of science would suffer instead of being advanced by the proposed arrangement.

SCHOOLS OF CHEMISTRY.

EXAMINING BOARDS.

UNIVERSITY OF LONDON.

CANDIDATES for any Degree granted by this University are required to have passed the Matriculation Examination, to which no candidate is admitted unless he has produced a certificate showing that he has completed his sixteenth year.

The Fee for this Examination is £2.

The Examination will be held on Monday, January 12th, 1874, and includes the following subjects:—

MATHEMATICS.

Arithmetic—

The ordinary Rules of Arithmetic.
Vulgar and Decimal Fractions.
Extraction of the Square Root.

Algebra—

Addition, Subtraction, Multiplication, and Division of Algebraical Quantities.
Proportion.
Arithmetical and Geometrical Progression.
Simple Equations.

Geometry—

The first four books of Euclid, or the subjects thereof.

NATURAL PHILOSOPHY.*

Mechanics—

Composition and Resolution of Statical Forces.
Simple Machines (*Mechanical Powers*): Ratio of the Power to the weight in each.
Centre of Gravity.
General laws of Motion, with the chief Experiments by which they may be illustrated.

Law of the Motion of Falling Bodies.

Hydrostatics, Hydraulics, and Pneumatics—

Pressure of Liquids and Gases, its equal diffusion, and variation with the depth.

* The Questions in Natural Philosophy will be of a strictly elementary character.

Specific Gravity, and modes of determining it.

The Barometer, the Syphon, the Common Pump and Forcing-Pump, and the Air-Pump.

Optics—

Laws of Reflection and Refraction.

Formation of Images by Simple Lenses.

CHEMISTRY.

Heat—its sources. Expansion. Thermometers—relations between different Scales in common use. Difference between Temperature and Quantity of Heat. Specific and Latent Heat. Calorimeters. Liquefaction. Ebullition. Evaporation. Conduction. Convection. Radiation.

Chemistry of the Non-Metallic Elements; including their compounds as enumerated below—their chief physical and chemical characters—their preparation—and their characteristic tests.

Oxygen, Hydrogen, Carbon, Nitrogen. Chlorine, Bromine, Iodine, Fluorine. Sulphur, Phosphorus, Silicon.

Combining Proportions by weight and by volume. General Nature of Acids, Bases, and Salts. Symbols and Nomenclature.

The Atmosphere—its constitution; effects of Animal and Vegetable Life upon its composition.

Combustion. Structure and Properties of Flame, Nature and Composition of ordinary Fuel.

Water. Chemical peculiarities of Natural Waters, such as rain-water, river-water, spring-water, sea-water.

Carbonic Acid. Carbonic Oxide. Oxides and Acids of Nitrogen. Ammonia. Olefiant Gas, Marsh Gas, Sulphurous and Sulphuric Acids, Sulphuretted Hydrogen.

Hydrochloric Acid. Phosphoric Acid and Phosphoretted Hydrogen. Silica.

CLASSICS.

The Greek and Latin Languages—

One Greek and one Latin subject, to be selected by the Senate one year and a half previously from the works of the undermentioned authors:—*

Homer One Book.

Xenophon One Book.

Virgil One Book of the Georgics, and one Book of the *Æneid*.

Horace Two Books of the Odes.

Sallust The Conspiracy of Catiline, or the War with Jugurtha.

Cæsar Two Books of the Gallic War.

Livy One Book.

Cicero De Senectute or De Amicitia, with one of the following Orations:—Pro Lege Manilia, either of the four Catilinarian Orations, Pro Archia, Pro M. Marcello.

Ovid One Book of the Metamorphoses, and one Book of the Epistles or Heroides.

The Paper in Greek shall contain passages to be translated into English, with questions in Grammar, History, and Geography. The Paper in Latin shall contain passages to be translated into English, with questions in History and Geography. A separate Paper shall be set containing questions in Latin Grammar, with simple and easy sentences of English to be translated into Latin.†

The English Language—

Orthography. Writing from Dictation. The Grammatical Structure of the Language.

Outlines of English History and Modern Geography—History of England to the End of the Seventeenth Century, with questions in Modern Geography.

The French or the German Language—

At the option of the Candidate.‡

* The Classical Subjects for 1874 are—For January, 1874:—*Homer*, Iliad, Book xxiv.; *Cicero*, De Senectute, and the Third Catilinarian Oration. For June, 1874:—*Xenophon*, Anabasis, Book v.; *Virgil*, Georgics, Book iv., and *Æneid*, Book vi.

† Special stress is laid on accuracy in the Answers to the Questions in Greek and Latin Grammar.

‡ At the next Matriculation Examinations (January, 1874; June, 1874; and January, 1875) credit will be given to Candidates for Credit in addition to either French or German.

The Papers in French and German shall contain passages for translation into English, and questions in Grammar (limited to the Accidence) on subjects furnished by those passages.

Candidates shall not be approved by the Examiners unless they have shown a competent knowledge in each of the following subjects:—

1. The Latin Language, with Grammar, History, and Geography.
2. Either the Greek Language, with questions in Grammar, History, and Geography; or the French or the German Language, with questions in Grammar.
3. The English Language, English History, and Modern Geography.
4. Mathematics.
5. Natural Philosophy.
6. Chemistry.

BACHELOR OF SCIENCE. (B.Sc.)

This degree is conferred on candidates who pass a satisfactory examination in Mathematics, Mechanical and Natural Philosophy, Botany, and Vegetable Physiology, Zoology, and Chemistry.

FIRST B.Sc. EXAMINATION.

No candidate (with the exception of such as have obtained Honours at the Matriculation Examination in the preceding January) is admitted to this examination within one academical year of the time of his passing the Matriculation Examination.

The Fee for this Examination is £5.

The examination will commence on the third Monday in July. It is conducted by means of printed papers; but the Examiners are not precluded from putting, for the purpose of ascertaining the competence of the candidates to pass, *viva voce* questions to any Candidate in the subjects in which they are appointed to examine.

The First Examination includes the following subjects:—

NATURAL PHILOSOPHY.

Heat—

Sources of Heat; conduction—convection.

Effects of Heat: expansion generally—of water—of gases and vapours; liquefaction; vaporisation; latent heat; expansive form of steam; dew-point; gases and vapours compared.

Specific Heat.

Thermometers; Pyrometers.

Heat in the Radiant state.

Electricity—

Sources of Electricity.

Static Electricity; dual character—insulation—induction—specific inductive capacity—equivalent antithetic states—disruptive discharge—convection; Electroscopes—Leyden Jar, &c.

Dynamic Electricity; Conduction—the electric current—derived currents—induction of currents; Voltaic Pile and other voltaic arrangements.

Thermo-Electricity; Electro-Thermometer.

Magnetism—

Magnets, the Earth, &c.; Induction—communication—retention—Magnetic relations of iron, steel, &c.

Electro-Magnetism—as in the spark—in conducting media—in soft iron; Magneto-Electricity; principle of Electro-magnetic and Magneto-Electric machines.

Terrestrial Magnetism.

INORGANIC CHEMISTRY.

Matter; simple and compound.

Elementary bodies classed. Metallic and Non-Metallic bodies.

Chemical combination and Mechanical Mixture. Solution.

Outlines of Crystallography. Isomorphism. Dimorphism. Allotropic conditions of matter. Chemical Affinity. Laws of Combination by weight and by volume, as deduced from the history of the individual elements. Equivalent

Numbers. Equivalent Volumes. Symbolical Notation, including questions on the Unitary System. Formulæ. Nomenclature.

Chemical actions produced under the influence of Heat. Nature of Combustion. Structures and Properties of Flame. Principles of Illumination. Chemical action of Light. Photography.

Oxygen. Ozone.

Hydrogen. Water.

Nitrogen. Chemical constitution of the Atmosphere. Diffusion of Gases. The Oxides of Nitrogen; Nitric Acid. Ammonia.

Chlorine, Bromine, and Iodine. Their compounds with Oxygen and Hydrogen. Theory of Bleaching.

Fluorine and Hydrofluoric Acid.

Sulphur, Sulphurous Acid. Manufacture and Chemical applications of Sulphuric Acid. Other Oxygen compounds of Sulphur. Sulphuretted Hydrogen.

Phosphorus. Oxygen and Hydrogen compounds of Phosphorus. Theory of Acids. Monobasic, Dibasic, and Tribasic Acids.

Carbon. Carbonic Oxide and Carbonic Acid. The principal Hydrogen compounds of Carbon. Manufacture of Coal Gas.

Silicon and Boron. Their compounds with the elements previously enumerated.

Metals. Characters of Metals as a class. Metallurgical Processes. Alloys. Classification of the Metals.

Potassium. Nitre. Gunpowder. Theory of the action of Gunpowder.

Sodium. Manufacture of Carbonate of Soda.

Barium. Strontium. Calcium. Mortars. Cements.

Magnesium. Aluminum. Glass. Porcelain.

Manganese. Iron. Composition and properties of Cast-Iron, Wrought-iron, and Steel. Chromium.

Cobalt. Nickel. Zinc. Cadmium.

Lead. Manufacture of White-Lead.

Copper. Mercury. Bismuth. Tin. Arsenic. Antimony.

Silver. Gold. Platinum.

Principal compounds of the Metals with the Non-Metallic Elements. Theory of Salts.

Principles of Mineral Analysis.

Principles of Electro-Chemistry.

For the First Examinations, a knowledge of Inorganic Chemistry only is necessary.

EXAMINATION FOR HONOURS.

Candidates for Honours in Chemistry are examined in any of the following subjects, at the option of the Examiners:—

Elementary Substances and their combinations.

Electro-Chemistry.

Radiant Chemical Action.

In the Examination for Honours, the Candidate, being not more than twenty-two years of age, who most distinguishes himself in Chemistry and Natural Philosophy, will receive an Exhibition of Forty pounds per annum for the next two years.

SECOND B.Sc. EXAMINATION.

This Examination commences on the fourth Monday in October. Candidates for this Examination who have not previously taken the degree of B.A. are required either to have passed the First B.Sc. Examination at least one Academical year previously, or to have passed the First M.B. Examination in this University.

The Fee for this Examination is £5.

This Examination embraces Organic Chemistry, including the following subjects:—

Ultimate Analysis of Organic Bodies. Calculation of Empirical Formulæ. Methods of controlling Empirical Formulæ. Determination of the Equivalents of organic acids and bases; examination of products of Decomposition; determination of the Vapour-Density of volatile bodies.

Law of Substitution. Compound Radicals. Homologous Series.

The Chemical History of the Cyanogen group. Cyanogen. Hydrocyanic Acid. Cyanic Acid and Urea. Fulminates. Cyanuric Acid. Sulphocyanic Acid. Chlorides of Cyanogen. Uric Acid.

Amylaceous and Saccharine Substances. Fermentation. Alcohol, Wine, Beer, Bread, &c.

Homologues of Alcohol. Ethers, simple and mixed. Oxidation of Alcohol. Aldehyd and Acetic Acid, and their homologues. Anhydrides, simple and mixed. Compound Ethers.

Diatomic Alcohols and their Acids. Glycol and Oxalic Acid and their homologues.

Triatomic Alcohols. Glycerin. Fatty and Oily bodies. Saponification.

Vegetable Acids;—the principal.

Ammonia and its Derivatives. Ammonium and Ammoniacal Salts. Amides and Amines: their Classification. The chief Natural Organic Bases.

Colouring Matters. Indigo and its derivatives. Principles of Dyeing.

The chief constituents of the Vegetable organism. Cellulose, Vegetable Fibrin, Albumen, Casein, Glutin, &c.

The chief constituents of the Animal organism. Animal Fibrin, Albumen, Casein, Gelatin. Blood, Milk, Bile, Urine, &c.

Decay, Putrefaction. Destructive Distillation.

The Chemical Principles of the process of Nutrition and of Respiration in Plants and Animals.

EXAMINATION FOR HONOURS.

The Candidate, not more than twenty-three years of age, who, in the Examination for Honours, most distinguishes himself in Chemistry, will receive Fifty pounds per annum for the next two years, with the style of University Scholar.

DOCTOR OF SCIENCE (D.Sc.).

This Examination is held within the first twenty-one days of June, and occupies four days.

No Candidate is admitted to the Examination for the Degree of D.Sc. until after the expiration of two Academical years from the time of his obtaining the Degree of B.Sc. in this University.

Candidates for the Degree of D.Sc. in any year, must give notice of their intention to the Registrar, and pay to him a Fee of Ten pounds, on or before the 1st of April.

Chemical Candidates can be examined either in Inorganic or Organic Chemistry; but no Candidate will be approved by the Examiners unless he has shown a thorough practical knowledge* of the *Principal Subject*, and a general acquaintance with the *Subsidiary Subject*, or *Subjects*, specified as belonging to the Branch so selected.

Inorganic Chemistry.

Principal Subject—Inorganic Chemistry.

Subsidiary Subjects—Either Organic Chemistry; or, Mineralogy, Crystallography, and Chemical Technology in its relations to Inorganic Chemistry.

Organic Chemistry.

Principal Subject—Organic Chemistry.

Subsidiary Subjects—Either Inorganic Chemistry; or, Chemical Technology, in its relations to Organic Chemistry, and the Chemistry of Animal and Vegetable Life.

THE EXAMINATIONS FOR WOMEN.

The standard of attainment expected at the General Examination is the same as that expected in the corresponding subjects at the Matriculation Examination; and the standard of attainment expected at the Special Examinations is the same as that expected at those Examinations for the B.A. and B.Sc. Degrees, of which the programmes correspond.

* It must be understood that the Candidate for the Degree of D.Sc. is expected to be so fully conversant with the principal subject he may select, as to be able to go through any examination test (whether theoretical or practical) of his acquirements in it that can be fairly applied.

In order that the requisite arrangements may be made, it is expected that intending Candidates will give notice of the optional subjects they select (where liberty of choice is allowed) not later than the 15th of March in each year.

GENERAL EXAMINATION.

The General Examination is held once in each year, and commences on the first Monday in May.

No Candidate is admitted to this Examination unless she has produced a Certificate showing that she has completed her seventeenth year. This Certificate must be transmitted to the Registrar at least *fourteen days* before the commencement of the Examination.

No Candidate is admitted to this Examination unless she has previously paid a Fee of Two Pounds to the Registrar. If a Candidate withdraw or fail to pass the Examination, the Fee is not returned to her, but she is admissible to any *two* subsequent General Examinations without the payment of any additional Fee, provided that she give notice to the Registrar at least *fourteen days* before the commencement of the Examination.

The Examination is conducted by means of printed papers; but the Examiners are not precluded from putting, for the purpose of ascertaining the competence of the Candidates to pass, *viva voce* questions to any Candidate in the subjects in which they are appointed to examine.

Candidates are not approved by the Examiners unless they have shown a competent knowledge in each of the following subjects:—

1. Latin, with Grammar, History, and Geography.
2. Any two of the following Languages:—Greek, French, German, Italian.
3. English Language, English History, and Geography (Physical and Topographical).
4. Mathematics.
5. Natural Philosophy.
6. Either Chemistry or Botany.

CERTIFICATES OF HIGHER PROFICIENCY.

Any Candidate who has passed the General Examination may be examined for a Special Certificate of Higher Proficiency in any one or more of the following subjects, either in the same year or in different years, provided that she give notice of her intention two calendar months before the commencement of the General Examination:—Latin, Greek, French, German, Italian, English, Mathematics and Mechanical Philosophy, Natural Philosophy and Chemistry, Botany, Human Physiology, Geology and Palæontology, Political Economy, Logic and Moral Philosophy, Harmony and Counterpoint.

The Examinations for these Certificates will commence on the day immediately following the third Monday in May.

CHEMICAL LECTURES AND LABORATORY INSTRUCTION.

UNIVERSITY COLLEGE.

FACULTY OF SCIENCE.

Dean.—Professor J. B. Sanderson, M.D., F.R.S.

Vice-Dean.—Professor A. W. Williamson, Ph.D., F.R.S.

The Session begins on Thursday, the 2nd of October, and ends about the end of June.

It is divided into three Terms, as follows:—Michaelmas term, from October 2nd until December 20th; Lent term, from January 7th, 1874, till March 18th; Summer term, for Lectures, from March 19th till June 9th, all inclusive.

Chemistry.—Professor Williamson, Ph.D., F.R.S.

Assistant Professor.—Charles Graham, D.Sc.

A. GENERAL COURSE.

Lectures daily, except Saturday, from 11 to 12 a.m., up to the last week in March.

Exercises on Tuesdays, Wednesdays, Thursdays, and Fridays, from 9 to 10 a.m.

Fee for the Whole Course of Lectures, £7 7s.; for the First or Second Half Course, separately £4 4s.; for the Second Half when the First has been taken, £3 3s.; Perpetual, £9 9s.; for the Organic Course alone, £2 2s.

Fee for the Exercise-Class—For the Course, £2 2s.; for the Half Course, £1 1s.

The Instruction in this Class is of two kinds, consisting partly of Experimental Lectures by the Professor, partly of exercises and personal instruction on the subject of the Lectures by the Assistant Professor.

Students cannot profit duly by attendance on the Lectures, unless they work at the subject of each Lecture so as to make it their own.

Attendance on the tutorial part of the Class enables Students to do their work more effectually and rapidly than they can do it by themselves.

The First Half of the Course to Christmas includes those parts of Chemistry which are required for the Matriculation Examination of the University of London. The Second Half of the Course, from January to March, includes the following subjects:—

Preparation and properties of the chief metals, including their characteristic reactions and most important salts. Detection of Metallic Poisons. Quantitative Estimation of Metals. Principles of Classification. Monatomic, Diatomic Metals, &c.

A weekly *viva voce* examination is held during the First Half Course and the commencement of the second Half Course.

Organic Chemistry.

This commences in the second week in February, and occupies Five Lectures weekly till about the end of March. It includes a study of the characteristics and metamorphoses of the chief organic acids, bases, alcohols, ethers, colouring matters, &c. Methods of ultimate and proximate analysis. Determination of molecular weights. Theory of types; of compound radicals. Phenomena of fermentation, &c.

Teachers of Chemistry are trained in the theory and practice of their profession. A two years' Course is absolutely requisite for this purpose; but Students will with advantage devote a longer period to it.

The first year is occupied with attendance on the Courses of Chemistry and of Analytical Chemistry. In the second year the Student again attends the Course of Chemistry, and is entrusted with teaching work in conjunction with the tutors of the Class. At the same time he continues to work in the Laboratory at analysis and original research.

In order to qualify themselves for rising to the higher ranks of the Profession, gentlemen remain for a further period, in which case they may obtain remunerative work in teaching through the recommendation of the Professor.

It must not, however, be supposed that a study of Chemistry alone, however complete, is sufficient to qualify a man to teach the Science effectively. A competent knowledge of Physics, Mathematics, and either French or German must necessarily be acquired at some period of his Student's Course.

B. ANALYTICAL AND PRACTICAL CHEMISTRY.

I. BIRKBECK LABORATORY.

The instruction in the Laboratory is intended for beginners as well as for more advanced students. It includes practice in the construction and use of apparatus for preparing the common gases, acids, bases, salts, &c.; study of the qualitative methods of detecting and separating mineral or organic bodies from one another; also quantitative analysis in the wet way, organic analysis, vapour densities, &c.; instruction in gas analysis.

More advanced Students are instructed in the methods of original research, especially in organic chemistry.

When accompanied or preceded by attendance on the Lectures on Chemistry, the Laboratory Course qualifies

Students in the application of Chemistry to the Manufacturing Arts, Metallurgy, Medicine, or Agriculture, &c. Instruction is given in the principles and processes of Gas Analysis.

The Laboratory and Offices are fitted up completely with the most improved apparatus and utensils for experimental research, both for beginners and for advanced Students. They are open daily, from 9 a.m. to 4 p.m., from the 4th of October until the end of July, with a short recess at Christmas and at Easter. Saturday, from 9 to 2.

Fees for the Session, 25 guineas; six months, 18 guineas; three months, 10 guineas; one month, 4 guineas; exclusive of the expense of materials. A deduction of about 40 per cent is made for Students who can attend only three fixed days per week.

A Gold Medal and Certificates of Honour are competed for by Students entered for the Session.

II. SUMMER COURSES.

I. Elementary Course.

About Forty Lessons, of one hour each, on Tuesday, Wednesday, Thursday, and Friday, from 11 to 12, commencing in the first week of May. Students are taught the construction and use of apparatus for the preparation of the most important gases, acids, &c. The characteristic tests for the presence of the common acids and bases, including the chief metallic and other poisons. Also the processes for separating these bodies from one another.

Solutions are frequently given in the class for investigation.

The first six weeks of the Course are occupied by the study of the chief non-metallic elements, and their simple compounds. Metallic salts, &c., are subsequently studied.

Fee, including the cost of materials and apparatus, for the Course, £4 4s.; Perpetual, £7 7s.

II. Senior Course.

This Course consists of Twenty Lessons, of two hours each, on Mondays and Saturdays, from 10 to 12, commencing in the first week in May.

The First Half of the Course includes tests for fixed and volatile organic acids, nitrogenised acids, sugars, glycerin, alkaloids, &c.

The Second Half of the Course includes tests for mineral poisons in organic mixtures; also tests for organic bodies, such as the alkaloids, when mixed with other organic substances.

Volumetric methods of the quantitative analysis of sugar and urea, chlorides, phosphates, hardness of water, alkalimetry, are practised.

Analyses of milk and of ashes of blood.

Fee, including cost of materials and apparatus, for the Course, £4 4s.; Perpetual, £7 7s.

C. SUMMER MATRICULATION COURSE.

Professor Williamson, F.R.S.

Assistant Professor.—Charles Graham, D.Sc.

This Course includes those parts of Chemistry which are required for the Matriculation Examination of the University of London.

The Course consists of about Twenty Lessons in Practical Chemistry, and of an equal number of Oral Lessons. The Practical Lessons include the preparation of the common gases and acids, &c., and the study of their characteristic properties in relation to the elementary laws of combination.

The other Lessons are chiefly devoted to those parts of the subject which require fuller oral explanation than is given in the Practical Lessons. They include numerous exercises and questions, to which answers in writing are given by the Students. These Lessons will begin on Tuesday, April 14, 1874, at 11 a.m.

The Class will meet on Tuesdays, Wednesdays, Thursdays, and Fridays, from 11 to 12; and some other meetings will be announced when the Class has assembled.

Fee, including cost of materials and apparatus, £4 4s.

SCIENCE AND ART DEPARTMENT OF THE
COMMITTEE OF COUNCIL ON EDUCATION,
SOUTH KENSINGTON,

AND

ROYAL SCHOOL OF MINES, JERMYN STREET.

The Lords of the Committee of Council on Education having transferred the instruction in Physics, Chemistry, Applied Mechanics, and Natural History, from the Royal School of Mines, in Jermyn Street, and the College of Chemistry, in Oxford Street, to the New Buildings, in Exhibition Road, South Kensington, the following Courses of Lectures, Demonstrations, and Practical Laboratory instruction are now given at South Kensington at the dates specified:—

Chemistry, by Professor Frankland, D.C.L., F.R.S. A Course of Forty Lectures on Inorganic Chemistry, commencing October 6, 1873. A Course of Thirty Lectures on Organic Chemistry, commencing January 19, 1874. Laboratory instruction, consisting of an elementary and an advanced Course, commencing on October 1. Fees—Lectures on Inorganic Chemistry, £4; Lectures on Organic Chemistry, £3; together, £6. Laboratory instruction—£12 for three months, £9 for two months, and £5 for one month.

Biology, by Professor Huxley, LL.D., F.R.S. A Course of Eighty Lectures on Biology (or Natural History, including Palaeontology), with Laboratory instruction, commencing October 6, 1873. Fee for the full Course, £10—For the Lectures only, £4; for the Laboratory instruction, £6.

Physics, by Professor Frederick Guthrie. The Course will consist of about Sixty Lectures, with Laboratory work on the subject of the Lectures. The Course will commence on February 16, 1874. Fee for Lectures alone, £4; fee for Lectures and Laboratory work, £10.

Applied Mechanics, by Professor Goodeve, M.A. The Course will consist of Thirty-Six Lectures, with Demonstrations, commencing on February 16, 1874. Fee for the Course, £4.

Besides the Students entering for the Associateship of the Royal School of Mines, and Teachers in Training, only such a limited number of occasional public Students will be admitted as can be accommodated. Letters with respect to the foregoing Courses should be addressed to the Secretary, Science and Art Department, South Kensington, London, S.W.

The instruction in Chemical Science embraces:—

(1). A Course of Lectures on Experimental Chemistry, with special reference to the applications of Chemistry in the Arts and Manufactures.

(2). A systematic Laboratory Course for the Practice of Chemical Analysis.

(3). An advanced Laboratory Course for technical applications of Chemical Analysis and for Chemical Research.

Chemical Laboratories.—The Laboratories for instruction in chemical manipulation, in qualitative and quantitative analysis, the technical application of analysis, and in the method of performing chemical researches, are under the direction of Dr. Frankland, and will be opened on Wednesday, October 1, 1873. The Laboratories at South Kensington Museum are now used for the instruction of the pupils of the Royal School of Mines.

There are three terms in the collegiate year, of three months each, commencing in the first week of October, January, and April, respectively. The Laboratory hours are from 10 a.m. to 5 p.m., with the exception of Saturdays, when the Laboratory closes at 2 o'clock.

Each Laboratory Student works independently, there being no classes. All operations are superintended by the Professor and his assistants. A table with drawers, cupboards, and shelves is appropriated to every pupil. The Institution supplies gas, fuel, and reagents. The larger and more expensive instruments of the Laboratory, such as air-pumps, thermometers, barometers, condensers

&c., may be used by the Students, who are responsible for their safety. The Students have to provide themselves only with the apparatus specified in the Laboratory regulations. More advanced Students engaged in private researches have to supply themselves with such materials as are not included amongst the ordinary reagents of the Laboratory.

The charge for instruction in the Chemical Laboratory is £12 for three months, £9 for two months, and £5 for one month. This charge does not include the fees for attending the Lectures.

Professor of Metallurgy.—Dr. Percy, F.R.S.

The course of instruction in Metallurgy consists of Lectures and Laboratory Practice, especially in Assaying.

The object of the Lectures is the communication of such instruction as the student may be able to apply to the greatest practical advantage when he may be subsequently engaged in conducting any metallurgical process.

Metallurgical Laboratory.—This Laboratory is conducted by Mr. R. Smith, under the direction of Dr. Percy, and is devoted to practical instruction in Metallurgy, especially in Assaying. The nature of this instruction will be adapted to the special requirements of the student. It comprises:—Assaying in all its branches, especially of the more important metals, such as iron, copper, lead, tin, alloys of silver and gold, &c.; and the examination of ores and metallurgical products.

The ability of the student to make trustworthy assays is in every case thoroughly tested; and no certificate of competency is given to a student who has not furnished satisfactory proof that he is able to obtain accurate results.

There are three terms in the collegiate year, of three months each. The Laboratory hours are from 10 to 4 during November, December, January, February; and from 10 to 5 during the other months, with the exception of Saturdays, when the Laboratory is closed.

The charge for instruction in the Metallurgical Laboratory is £15 for three months, £12 for two months, and £7 for one month.

Lectures to Working Men.—Short Courses of Lectures at suitable periods of the year are given in the evening to Working Men. These courses are systematic, and arranged so as to illustrate, within a period of two years, the principal subjects taught at the Institution. Those for the ensuing Session include Natural History, Geology, and Mineralogy.

EXAMINATIONS IN CONNECTION WITH THE
DEPARTMENT OF SCIENCE AND ART, SOUTH
KENSINGTON.

A sum of money is voted annually by Parliament for scientific instruction in the United Kingdom. The object of the grant being to promote instruction in Science, especially among the Industrial classes, by affording a limited and partial aid or stimulus towards the founding and maintenance of Science schools and classes.

The following are among the Sciences towards instruction in which aid is given:—Acoustics, Light, Heat, Magnetism, and Electricity, Inorganic Chemistry, Organic Chemistry, Geology, Mineralogy, Mining, Metallurgy.

The assistance granted by the Science and Art Department is in the form of—1. Public Examinations, in which Queen's Medals and Queen's Prizes are awarded, held at all places on complying with certain conditions. 2. Payments on results to teachers. 3. Scholarships and Exhibitions. 4. Building Grants. 5. Grants towards the purchase of apparatus, &c.

KING'S COLLEGE.

Professor of Chemistry and Practical Chemistry.—C. L. Bloxam, F.C.S.

Demonstrator.—W. N. Hartley, F.C.S.

The Session commences on the 1st of October. Students of the first and second years are admitted to the Course of Theoretical and Applied Chemistry. The Course commences with a view of the forces which concur to

the production of Chemical Phenomena, after which the laws of Chemical Attraction are discussed, and the Non-Metallic Elements and their principal compounds are described.

The metals and their principal compounds are next examined, care being taken to point out the applications of the Science to the Arts, and the processes of the different Manufactures of Metallurgy, and of Domestic Economy, are explained and illustrated.

Examinations of the Class, both *viva voce* and by written papers, are held at intervals during the Course, at the usual Lecture hour.

Third Year.—Students who have completed six Terms in this Department are admitted to a Course of Practical Chemistry, consisting of Twelve Demonstrations in each term; and they go through a course of Manipulation in the most important operations of Chemistry, including the first steps of Analysis.

Any Student of this Department may be admitted to this Class at any period of his study, on payment of an extra fee.

Analytical and Experimental Chemistry.—Besides the Course of Chemical Lectures and the Summer Class of Practical Chemistry, provision is made for those Students who wish to become more minutely acquainted with the practical details of the Science. By means of this Class each Student is enabled to familiarise himself with the methods of analysis and research. After passing through a preliminary course of analytical operations, each Student devotes himself to such portions of the science as are most interesting to himself, or most likely to be practically useful to him. The Daniel Scholarship of £20, tenable for two years, is given every alternate year for original research in the Laboratory.

The Fees for admission to the Laboratory Class, exclusive of materials, are, for one month, £4 4s.; for three months, £10 10s.; for six months, £18 18s., &c.

EVENING CLASSES.

Classes for Evening Instruction are held at King's College from October to March, and during April, May, and June.

The Classes include one for the Elements of Chemistry and one for Practical Chemistry.

The fee for the former is £1 11s. 6d.; for the latter, £2 2s. The classes meet twice a week.

THE SCHOOL OF PHARMACY,

17, BLOOMSBURY SQUARE, W.C.

(IN CONNECTION WITH THE PHARMACEUTICAL SOCIETY.)

The Session commences on October 1st, and extends to the end of July.

LECTURES ON CHEMISTRY AND PHARMACY, BY DR. REDWOOD.

These Lectures will be delivered on Monday, Tuesday, and Wednesday mornings, at 9 o'clock.

Fees.—One Course, £2 2s. An entire Session—two Courses, £3 3s. Perpetual admission, £4 4s.

Also Lectures on Botany and Materia Medica, by Professor Bentley. The first and second parts of this course, extending over the winter months, will be delivered at 17, Bloomsbury Square, on Friday and Saturday mornings, at 9 a.m. The third part of the course, on Systematic Botany, will be delivered at the Royal Botanic Gardens, Regent's Park, at 8 a.m.

Fees.—Botany and Materia Medica, one Course, £1 11s. 6d.; two Courses, £2 12s. 6d. Systematic and Practical Botany, £1 1s. each Course. Sessional Fee for the three Courses, £3 3s.

Practical Chemistry.—The suite of Laboratories for Practical Instruction in General and Pharmaceutical Chemistry will be opened on October 1st, under the direction of Professor Attfield, Ph.D.

Demonstrator.—John Moss, F.C.S. Fee for the entire Session of ten months, Twenty-five Guineas. The Laboratories are open from 10 a.m. till 5 p.m. Students can enter at any period during the Session,

Two Scholarships (the Jacob Bell Memorial Scholarship) of Thirty Pounds a year each, are open to competition annually in July.

Students have free admission to the Library and Museum.

CITY OF LONDON COLLEGE, LEADENHALL STREET, E.C.

The Annual Courses consist of three terms, each averaging ten Experimental Lectures. Fee, 5s. per term.

Subjects:—Junior Class, Chemistry—First year, Non-Metals; second year, Metals and (time permitting) Elements of Organic Chemistry. Senior Class, 7 to 8 p.m., Practical Analysis.

BIRKBECK LITERARY AND SCIENTIFIC INSTITUTION,

EVENING CLASSES.

Chemistry, Elementary.—Mr. G. Chaloner. Thirty Lectures. Tuesday, 7.30 to 8.30, commencing October 7.

Advanced.—Tuesday, 9 to 10. Thirty Lectures.

Practical Chemistry and Analysis.—From 8 to 10, Saturday evenings, commencing October 11.

ROYAL POLYTECHNIC INSTITUTION,

309, REGENT STREET, W.

The Scientific Department is under the direction of Professor E. V. Gardner, F.A.S., F.S.A., who is assisted in his duties by gentlemen of known competency.

Instruction in classes is given in Chemistry, Electricity, Galvanism, Geology, Photography, &c. These and the various subjects required by the different Examining Boards are taught and thoroughly demonstrated. To this purpose the extensive School of Apparatus, as well as that employed for illustrating the Public Lectures, is made use of.

Private Courses of study can also be pursued under the direction of Professor Gardner, who has constructed Private Class Rooms and Laboratories.

Provision has been made for Ladies desirous of studying the Sciences.

The Patent Department is valuable to Inventors, as they can be provided with the necessary apparatus to pursue their enquiries, or they may have a full investigation conducted.

ROYAL VETERINARY COLLEGE, CAMDEN TOWN.

Chemical Professor.—Mr. R. V. Tuson.

BERNERS COLLEGE OF EXPERIMENTAL SCIENCE,

44, BERNERS STREET, W.

Under the direction of Professor E. V. Gardner, F.A.S. F.S.A.

The Class Rooms and Laboratories are open to private students, who can arrange to pursue any branch of study at their own convenience with the advantage of School of Apparatus for illustration and experiment.

The Classes during the Session embrace the subjects of Chemistry, Magnetism, Electricity, Galvanism, Geology, Photography, Botany, Steam, &c.

A Course of study is arranged to meet the requirements of gentlemen preparing for Matriculation, for the various Governmental Examinations and Examining Boards.

Analysis of manures and other substances and Assays are performed, and much attention is paid to original experiments and investigations connected with Patents and Inventions.

Mathematics.—The Classics, Modern Languages, and the branches of knowledge usual for a successful examination are in the hands of competent teachers.

NORTH LONDON SCHOOL OF CHEMISTRY AND PHARMACY,

54, KENTISH TOWN ROAD, N.W.

Conducted by Mr. J. C. Braithwaite.

The Session 1873-1874 commences on the 1st of

October, when the Laboratory will be open for Instruction in Practical Chemistry.

The Classes for Chemistry, Materia Medica, Botany, and Latin, meet at 8 p.m. Fee to either Class 10s. 6d. per month.

The Botanical Garden affords facilities to Students desirous of acquiring a practical-knowledge of Botany. During the Season Botanical Excursions are made every Saturday at 10 a.m.

As each Pupil works independently, he can enter at any period to either Classes or Laboratory.

SOUTH LONDON SCHOOL OF CHEMISTRY, 325, KENNINGTON ROAD.

This School was re-opened on September 8th in a new building specially erected for and adapted to the study of Chemistry and its Allied Sciences. The subjects taught include Chemistry, Botany, Physics, Latin, Materia Medica, and Pharmacy, for fifty students. All apparatus and chemicals are provided for the students. There is also a special department for instruction in Food Analysis at the Central Public Laboratory, Kennington Cross, under the personal supervision of the Director, who has been appointed Public Analyst. The Chemical portion of the Course consists of Ten Months' Lectures on Inorganic and Organic Chemistry. The Lecturer is Dr. John Muter, F.C.S., and the hour is 10 a.m. daily. The Laboratory is open daily for practical instruction from 10 till 4. Secretary, Mr. W. Baxter.

LECTURES AT LONDON MEDICAL SCHOOLS.

ST. BARTHOLOMEW'S HOSPITAL & MEDICAL COLLEGE.

WINTER SESSION.

Lecturer.—Dr. W. J. Russell, F.R.S. Monday, Wednesday, and Friday, at 10 a.m. One course, £5 5s.

SUMMER SESSION.

Practical Chemistry.—Dr. W. J. Russell, F.R.S. Monday, Tuesday, and Friday, from 11 to 1. One course, £2 2s.

CHARING CROSS HOSPITAL AND COLLEGE.

WINTER SESSION.

Lecturer.—Mr. C. W. Heaton, F.C.S. *Demonstrator.*—T. Bolas, F.C.S. Monday, Thursday, and Friday, at 11. One session, £5 5s.

The Laboratory is open daily.

SUMMER SESSION.

Practical Chemistry.—Mr. Heaton, F.C.S. *Demonstrator.*—T. Bolas, F.C.S. Monday and Friday. One session, £2 2s.

Special Evening Classes. Advanced Chemistry, Tuesday and Thursday, at 7 p.m. Fee, £2 2s. per month.

ST. GEORGE'S HOSPITAL.

WINTER SESSION.

Lecturer.—Dr. H. M. Noad, F.R.S. Tuesday, Thursday, and Saturday, at 11.30. One course, £6 6s.

SUMMER SESSION.

Practical Chemistry.—Dr. Noad, F.R.S., Monday, Wednesday, Thursday, Friday, at 10. One course, including the use of apparatus and materials, £4 4s.

GUY'S HOSPITAL.

WINTER SESSION.

Lecturers.—Dr. Debus, F.R.S., and Dr. Stevenson. Tuesday, Thursday, and Saturday, at 11. One course, £4 4s.

SUMMER SESSION.

Practical Chemistry.—Dr. Debus, F.R.S. Monday, Wednesday, and Friday, from 10 to 1. One course, £4 4s.

Practical Instruction is also given in the Laboratory by Drs. Debus and Stevenson during the Winter Session,

LONDON HOSPITAL.

Lectures on Chemistry.—Henry Letheby, M.B., and C. Meymott Tidy, M.B. Monday, Wednesday, and Friday, at 10.30 a.m. One session, £7 7s.

Practical Chemistry.—Dr. Letheby, M.B. Monday, Thursday, and Saturday, at 9 a.m. One session, £3 3s.

ST. MARY'S HOSPITAL.

WINTER SESSION.

Lecturer.—Dr. C. R. A. Wright, F.C.S. Monday, Tuesday, Thursday, and Friday, at 9 a.m. £5 5s.

SUMMER SESSION.

Practical Chemistry.—Dr. C. R. A. Wright, F.C.S. *Inorganic Course.*—Arranged for the requirements of the London University Preliminary Scientific Examination. Tuesday, Friday, and Saturday, at 9 a.m. Fee, £3 3s.

Organic Course.—Arranged to meet the requirements of the London University First M.B. Examination. Tuesday and Friday at 10 a.m. £3 3s.

MIDDLESEX HOSPITAL.

WINTER SESSION.

Lecturer.—Mr. Heisch. Monday, Tuesday, Friday, and Saturday, at 11. One session, £6 6s.

SUMMER SESSION.

Practical Chemistry.—Mr. Heisch. Monday, Wednesday, and Friday, at 11. One session, £3 3s.

ST. THOMAS'S HOSPITAL.

WINTER SESSION.

Lecturer.—Dr. A. J. Bernays. Wednesday, Thursday, and Friday, at 9. One course, £5 5s.

SUMMER SESSION.

Practical Chemistry.—Dr. A. J. Bernays. Tuesday and Thursday, 10 to 12; Friday, 11; Saturday, 10 to 1. One course, £3 3s.

WESTMINSTER HOSPITAL.

WINTER SESSION.

Lecturer.—Dr. A. Dupré, F.C.S. Tuesday and Thursday, at 3 p.m.; Friday, at 10 a.m. One course, £5 5s.

SUMMER SESSION.

Practical Chemistry.—Dr. A. Dupré, F.C.S. Monday, Wednesday, and Friday, at 10 a.m. One course, £3 3s.

TEACHERS OF CHEMISTRY IN LONDON.

Mr. Henry Matthews, F.C.S.—Laboratory, 60, Gower Street, Bedford Square. Instruction in all branches of Practical Chemistry, particularly in its application to Medicine, Agriculture, and Commerce. Laboratory open daily, except Saturday, from 10 to 5; on Saturday, from 10 to 1.

Mr. John Newlands, F.C.S.—Laboratory, 13, Knowle Road, Brixton, S.W. Gives practical instruction in Analysis, and prepares gentlemen for various public examinations.

Mr. A. Vacher.—20, Great Marlborough Street, Regent Street.

UNIVERSITY OF OXFORD.

Professor of Chemistry.—Dr. Odling, F.R.S.

Demonstrator.—E. Madan, M.A.

A commodious Laboratory is attached to the New Museum.

Scholarships of about the value of £75 are obtainable at Christ Church, Magdalen, and other Colleges, by competitive examination in Natural Science.

UNIVERSITY OF CAMBRIDGE.

Professor of Chemistry.—G. D. Liveing, M.A.

Demonstrator.—J. W. Hicks, M.A.

LECTURES IN MICHAELMAS TERM.

Chemistry, general principles, by the Professor, on Mondays, Wednesdays, and Fridays, at 12.

Spectroscopic Analysis, by the Professor.
Practical Chemistry, by the Demonstrator, daily.
Organic Chemistry, by Mr. Main, at St. John's College.
Volumetric Analysis, by Mr. Apjohn, at Gonville and Caius College.

LECTURES IN LENT TERM.

Chemistry, general principles continued, by the Professor, on Mondays, Wednesdays, and Fridays, at 12.
Quantitative Analysis, by the Professor, same days, at 1.
Practical Chemistry, by the Demonstrator, daily.
Elementary Chemistry, by Mr. Main, at St. John's College.
Quantitative Analysis of rarer elements, by Mr. Apjohn, at Gonville and Caius College.

LECTURES IN EASTER TERM.

History of Chemical Philosophy, by the Professor, on Mondays, Wednesdays, and Fridays, at 12.
Quantitative Analysis, same days, at 3.
Elementary Inorganic Chemistry, by the Demonstrator.
Chemistry, continued, by Mr. Main, at St. John's College.
Organic Analysis, by Mr. Apjohn, Gonville and Caius College.

The Chemical Laboratory of the University is open daily from 10 a.m. until 6 p.m., for the use of students, under the direction of the Professor. The Demonstrator attends there daily to give instruction in manipulation, alternately in the morning and afternoon.

PROVINCIAL SCHOOLS.

BIRMINGHAM.—MIDLAND INSTITUTE.

Lecturer on Chemistry.—Mr. C. J. Woodward, B.Sc. Tuesday and Thursday, at 8 p.m.
Practical Chemistry.—Mr. C. J. Woodward, B.Sc. Saturday, 3 to 6, and 6.30 to 9.30 p.m.

BIRMINGHAM.—QUEEN'S COLLEGE.

WINTER SESSION.

Professor of Chemistry.—Alfred Hill, M.D., and A. G. Anderson. Tuesday, Thursday, and Friday, at 12.

SUMMER SESSION.

Practical Chemistry.—Professor A. G. Anderson. Thursday and Friday, at 2 p.m.

BRISTOL.—BRISTOL MEDICAL SCHOOL.

WINTER SESSION.

Lecturer.—Mr. Thomas Coomber, F.C.S. Monday, Tuesday, Wednesday, and Thursday, at 8.15. One Course, £5 5s.

SUMMER SESSION.

Practical Chemistry.—Mr. T. Coomber, F.C.S. Daily, except Saturday, at 8 a.m. One Course, £3 3s.

ROYAL AGRICULTURAL COLLEGE,
CIRENCESTER.

CHEMICAL DEPARTMENT.

Professor.—A. H. Church, M.A. Oxon.

Assistant.—R. C. Woodcock, F.C.S.

The Autumn Session commenced on the 13th of August; it divides on the 6th of October, and terminates about the 18th of December.

The Chemical instruction comprises Three Courses of Lectures and Laboratory Practice:—

- (1). 32 Lectures on Inorganic Chemistry.
- (2). 32 Lectures on Organic Chemistry.
- (3). 24 Lectures on Agricultural Chemistry.
- (4). 32 Lessons on Chemical Manipulation.
- (5). 32 Lessons on Qualitative Analysis.
- (6). 32 (or more) Lessons on Quantitative Analysis.

Catechetical Lectures are also given, while analyses of manures, oil-cakes, minerals, soils, waters, &c., are daily performed in the College Laboratories, and Chemo-Agricultural researches undertaken by the more advanced

Students, under the immediate direction of Professor Church.

The text-books used are Church's "Laboratory Guide," Roscoe's "Chemistry," and Church and Dyer's edition of "How Crops Grow."

LIVERPOOL ROYAL INFIRMARY SCHOOL OF
MEDICINE.

Lecturer on Chemistry and Toxicology.—Dr. J. Campbell Brown.

Course of 100 Lectures. Monday, Tuesday, Thursday, and Friday, at 10.15. £5 5s.

Technological and other non-Medical Students may take out any of the divisions separately—Fee, £1 1s.; but no certificates will be given until the whole Course has been attended.

Practical Chemistry.—The new Laboratories will be open on November 1 for the reception of Students, when those who desire to prosecute Practical Chemistry, analysis, or original research, will be provided each with a separate working bench and cupboard, with tests, fuel, water, and gas. Fees, from £2 2s. to £10 10s. per quarter.

Summer Practical Chemistry Course.—Fee, £3 3s.

A Class for the Practical study of Organic Chemistry will be formed during either the Winter or Summer Session. Fee, £3 3s., including materials and apparatus.

Gentlemen who are not Students of the School are also admitted to the Laboratory and Lectures.

The Laboratory is open daily from 10 to 4 (except Saturday), for the study of Practical Chemistry, and for Analysis.

ANALYTICAL LABORATORY AND SCHOOL OF
TECHNICAL CHEMISTRY.

7 and 9, HACKIN'S HEY, LIVERPOOL.

Conducted by Mr. A. Norman Tate.

Hours of attendance, 9.30 a.m. to 5 p.m. (Saturdays, 9.30 a.m. to 1 p.m.). Pupils may enter at any time and for any term.

Fees—Three months, £15 15s.; six months, £26 6s.; twelve months, £52 10s.

The Laboratory is also open from October to end of April two evenings per week for practical work.

Lectures one evening each week.

A separate working bench is provided for each Student, and he is also supplied with all ordinary chemicals, gas, fuel, and the more substantial portions of Laboratory apparatus, but must provide himself with test-tubes, beakers, and other apparatus of a fragile nature.

In addition to the ordinary chemical studies, the Course of instruction will, as far as possible, comprise all such studies as may be required for the successful prosecution of the particular branch or branches of Applied Chemistry in which the pupil is to engage; as, for example, in the case of one intended for manufacturing pursuits, he would study architectural and mechanical drawing, so far as is required for the preparation of plans, &c., of chemical apparatus and manufactories, the nature and use of building materials, and the scientific principles and practical rules involved in building and constructive operations, and other scientific and practical information required in the arrangement, construction, and management of chemical manufactories, and the application of Chemistry to industrial pursuits.

LIVERPOOL.—OPERATIVES' SCIENCE CLASSES.

(IN CONNECTION WITH THE GOVERNMENT DEPARTMENT OF SCIENCE AND ART, AND THE OPERATIVE TRADES' HALL, LIVERPOOL).

Chairman.—Mr. James Samuelson.

Secretary.—Mr. M. Fitzpatrick, 62, Seel Street.

Session extends from October 3, 1873, to end of April, 1874.

Classes meeting at 9, Hackin's Hey—Lecture Class, Friday evenings, 7 to 8 p.m.; Laboratory Practice, Friday evenings, 8 to 10 p.m. Teacher, Mr. Norman Tate.

Class meeting at St. Mary's Schools, Kirkdale—Lecture Class, Thursday evenings. Teacher, Mr. Gordon.

COLLEGE OF CHEMISTRY, LIVERPOOL.

Founder.—Dr. Muspratt, M.D., &c.

Principal.—Mr. Martin Murphy, F.C.S., Professor of Chemistry.

The Course of instruction given in the College of Chemistry comprises the teaching of Chemistry as a science, and the general application of chemical knowledge; also the teaching of the principles of those branches of physics which are allied with Chemistry, such as light, heat, electricity, &c.

Particular attention is devoted to instruction in the practice of systematic analytical operations, whereby Students will be enabled to determine accurately the general and proximate constituents of substances, and so arrive at a knowledge of their nature and properties.

Instruction in the application of chemical data to medicine and agriculture, and to the chemical and metallurgical operations, comprising Technology, will be given, to qualify Students for these avocations.

The Students will invariably be controlled and directed in their study and work by the Principal and competent assistants. Ample Laboratory accommodation is provided for Students, and such general appliances as will facilitate their progress in acquiring a knowledge of the specialities taught in the College.

The Students' Laboratories are open throughout the year. Hours of attendance—From 10 a.m. to 5 p.m. daily. Fees—10 guineas per quarter of three months, or 35 guineas per annum, payable in advance. Students provide all their own apparatus and books.

Medical and Pharmaceutical Students are admitted for one hour per day. Fee for three months, £2 2s.

A Course of Lectures will be delivered to the Students during the winter months. Evening Classes.

Certificates of attendance recognised by the University and Apothecaries' Hall of London, and Apothecaries' Hall of Ireland.

LEEDS SCHOOL OF MEDICINE.

WINTER SESSION.

Lecturer.—Mr. Thomas Fairley, F.C.S.

Daily, except Wednesday and Saturday, at 11 a.m. First Session, £4 4s. Second Session, £3 3s.

SUMMER SESSION.

Practical Chemistry.—Mr. Fairley, F.C.S.

Mondays and Tuesdays, 9.30 to 11. Each Course, £3 3s.

General Chemical Students.—The Laboratories are open daily, under the direction of Mr. Fairley, for the instruction of General Students in Chemical Manipulation, Technical Chemistry, and all branches of analysis; and also for the use of gentlemen wishing to pursue special chemical researches.

The fees, payable in advance to the Treasurer, are as follows:—For one month, £4 4s.; for two months, £7 7s.; for three months, £10 10s.; for four months, £13 13s.; for five months, £15 15s.; for six months, £17 17s.; for nine months, £21. Special fees will be charged to Students who do not wish to work every day in the week.

The Chemical Museum contains minerals, metallic ores and metals, rare chemical substances, and illustrations of the most important chemical manufactures in their different stages.

Curator.—Mr. Scattergood.

LEEDS MECHANICS' INSTITUTION AND LITERARY SOCIETY'S LABORATORY.

Chemical Classes and Laboratory for Instruction in Elementary, Practical, and Analytical Chemistry, commence on Friday, September 26, at 8 p.m.

Lecturer.—Mr. George Ward, F.C.S., with Assistants.

HIGH HARROGATE COLLEGE, YORKSHIRE.

Professor of Chemistry.—Mr. W. G. Mason, F.C.S., Certificated Science Teacher.

MANCHESTER GRAMMAR SCHOOL.

CHEMICAL DEPARTMENT.

Professor.—Francis Jones.

Instruction is given in Inorganic Chemistry, Organic Chemistry, Metallurgy, and Analytical Chemistry. There is a lecture-room and second Laboratory, affording accommodation for seventy-two Students.

MANCHESTER ROYAL SCHOOL OF MEDICINE.

(INCORPORATED WITH OWENS COLLEGE).

Lecturer on Chemistry and Practical Chemistry.—Henry E. Roscoe, B.A., Ph.D., F.R.S.

The usual Course for the Medical Boards.

Pending the completion of Medical School Buildings, in immediate proximity to the new College, the School will be conducted as heretofore in the old premises, 10, Faulkner Street, with the exception of the following Courses, which will be given in the Owens College, Oxford Road:—Chemistry and Physiology, Systematic and Practical, in the Winter Session, and Botany and Practical Chemistry in the Summer Session.

OWEN'S COLLEGE, MANCHESTER.

Chemistry.—Professor H. E. Roscoe, B.A., Ph.D., F.R.S., F.C.S.

Senior Demonstrator.—Mr. C. Schorlemmer, F.R.S.

Junior Demonstrator and Assistant Lecturer.—Mr. W. Dittmar, F.R.S.E.

Assistant Demonstrators.—Mr. W. Carleton Williams and Mr. Harry Grimshaw.

Experimental Chemistry Lectures.—Monday, Tuesday, Wednesday, Thursday, and Friday, from 11.30 a.m. to 12.30 p.m., during Michaelmas and Lent Terms.

The instruction in Theoretical Chemistry is given by means (a) of Experimental Lectures and (b) of Tutorial classes. The former will be delivered by Professor Roscoe on the days above-named.

Inorganic Chemistry.—Comprising (1) the laws of Chemical Combination; (2) A description of the Physical and Chemical properties, and the mode of preparation of the Non-Metallic Elements and of their compounds; (3). The Chemistry of the Metals and of their most important compounds.

Organic Chemistry.—Giving the composition and relations of the best defined groups of organic bodies and the laws regulating their formation.

The Tutorial Classes, conducted by Mr. Dittmar, will meet for recapitulation and for the correction of the written exercises, given out in the lectures during Michaelmas and Lent Terms, as follows:—1. *Junior Tutorial*. For First Year's students and those preparing for Matriculation, on Wednesdays, from 1.30 to 2.30 p.m. 2. *Senior Tutorial*. For Second Year's students and those preparing for the Science Degrees, on Saturdays, from 11.30 a.m. to 12.30 p.m. 3. *Medical Tutorial*. Specially adapted to the requirements of Medical students, on Fridays, from 12.30 to 1.30 p.m.

Regular students in the First Year's Arts and Science courses will be entitled to attend during the Michaelmas Term only, in the Second Year's Science and Engineering courses during both Terms.

Fee, for the complete course, £4 14s. 6d.; for either half, £2 12s. 6d.

Technological Chemistry.—Wednesday, from 2.30 to 3.30 p.m.

The chemical principles involved in the most important Chemical Manufactures will chiefly be considered in this course. The subject will be discussed as follows:—

1. Ten lectures on the Modes of Producing and Utilising Heat and Light, by Mr. Dittmar.

2. Ten lectures on Water and Air and the Chemistry of the Alkali Manufacture, by Professor Roscoe.

3. Ten lectures on the Chemistry of Colouring Matter, Dyeing, and Calico Printing, by Mr. Schorlemmer.

Students attending this class must be acquainted with the principles of chemical science.

Fee, £1 11s. 6d.

Organic Chemistry.—Lecturer, Mr. C. Schorlemmer, F.R.S., Tuesday and Thursday, from 2.30 to 3.30 p.m., and Friday, from 3.30 to 4.30 p.m.

The subject of this course is the Chemistry of the Carbon Compounds, wherein the branch of Organic Chemistry is more fully and completely treated than in the general course in Experimental Chemistry.

Fee, £3 10s.

Chemical Philosophy.—Lecturer, Mr. C. Schorlemmer, F.R.S., Saturday, from 9.30 to 10.30 a.m.

Sketch of the History of Chemistry; Development of Modern Chemistry; Chemical Laws and Theories; Relation of Chemistry to Physics.

Fee, £1 11s. 6d.

Lecture Class Analytical Chemistry.—Mr. W. Dittmar, F.R.S.E. Tuesday, from 4.30 to 5.30 p.m.

This course will treat of the methods of Qualitative and Quantitative Analysis, and is intended to supplement the instruction in Practical Chemistry.

All first year's Laboratory students are required to attend, and to answer the written exercises and the *viva voce* questions given in this class.

Fee, £1 11s. 6d.

Analytical and Practical Chemistry.

LABORATORY CLASS.

The aim of this course is to make the student practically acquainted with chemical science, to enable him to conduct analysis and original research, and to fit him for applying the science to the higher branches of Art, Manufactures, and Agriculture. To accomplish this, an attendance of not less than four days per week during three whole sessions is as a rule necessary. It is very advisable that each Laboratory student should attend, or should have attended, the course of Lectures on Theoretical Chemistry; and it is also recommended that second year's Laboratory students should attend one of the classes in Practical Physics.

The College Laboratory will be open for students daily from 9.30 a.m. until 4.30 p.m., except on Saturdays, when it will be closed at 12.30. The Laboratory is fitted with every convenience for the prosecution of Practical Chemistry, all branches of Qualitative and Quantitative Analysis, and original Research. Each student is provided with a separate working table, a set of tests, fuel, water, and gas, free of expense; but he is required to find his own apparatus, a few of the more expensive reagents, and the chemicals required for his experiments. Other apparatus or instruments of a more expensive description may be obtained on loan from the Laboratory Steward, subject to regulations to be prescribed by the Professor.

Fees for the Session.—For six days per week, £21; for four days per week, £17 17s.; for three days per week, £13 13s.; for two days per week, £9 9s.; for one day per week, £5 5s.

Students entering the Laboratory class at or after Christmas will be charged two-thirds of the fees for the whole session.

Fees for Shorter Periods.—For six days per week: For six months, £17 17s.; for five months, £15 15s.; for four months, £13 13s.; for three months, £10 10s.; for two months, £7 7s.; for one month, £4 4s.

The Lectures on Chemistry in Owen's College are recognised by the University of London for its Medical Degrees, by the Royal College of Surgeons, and by the Apothecaries' Hall.

EVENING CLASSES.

Chemistry.

First Lecture Course.—(The Non-Metallic Elements).—Professor Roscoe. Monday, from 8.30 to 9.35 p.m.

Second Lecture Course.—(The Metals).—Mr. Carnelly. Friday, from 8.35 to 9.35 p.m.

Third Lecture Course.—(Organic Chemistry).—Mr. Schorlemmer. Thursday, from 8.35 to 9.35 p.m.

Laboratory Courses.—Professor Roscoe and Mr. Dittmar. Monday, from 6 to 8.30 p.m.

COLLEGE OF PHYSICAL SCIENCE, NEWCASTLE.

(IN CONNECTION WITH THE UNIVERSITY OF DURHAM).

Professor of Chemistry.—A. Freire-Marreco, M.A.

Demonstrator.—E. Haigh.

Junior Division—General Principles of Chemistry History of the Non-Metallic Elements.

History of the Metals and their more important compounds; Principles of Qualitative Analysis, Monday, Wednesday, and Friday, at 11 a.m.

Senior Division—Elements of Organic Chemistry, Tuesdays, at 11 a.m. Applied Chemistry, Thursdays, at 11 a.m. Fee, £5 5s.

Practical Chemistry.—The Laboratory is open from 10 a.m. to 1 p.m., and from 2 to 5 p.m., except on Saturday, when it closes at 1 p.m.

Laboratory Fees.—Students working six days per week, five guineas per term. Students working alternate days, three guineas per term. Students working one day per week, one guinea per term.

Evening Classes.—Prof. A. Freire-Marreco, M.A., Twenty Lectures on Inorganic Chemistry, Mondays, at 7.45, commencing October 20, 1873.

BOROUGH ANALYST'S LABORATORY, 1 and 3, SURREY STREET, SHEFFIELD.

Mr. A. H. Allen, F.C.S., delivers a Course of Thirty Lectures on Inorganic Chemistry and Metallurgy. Day and Evening Classes for the practice of Analytical Chemistry and Assaying.

SHEFFIELD SCHOOL OF MEDICINE.

A Course of Forty-five Lectures on Inorganic and Organic Chemistry will be delivered during the Winter Session, by A. H. Allen, F.C.S.

The Summer Course of Practical Chemistry is conducted by Mr. Allen.

SCOTLAND.

UNIVERSITY OF EDINBURGH.

Professor of Chemistry.—Dr. A. Crum Brown, F.R.S.

SCHOOL OF MEDICINE, EDINBURGH.

Lecturer on Chemistry.—Dr. Stevenson Macadam, F.R.S.E.

The Courses of Instruction in Chemistry include its applications to Medicine, Agriculture, and the Industrial Arts; and they qualify for the University of Edinburgh and other Universities, the Royal Colleges of Physicians and Surgeons, the Navy, Army, and Indian Medical Service, and the other Medical and Public Boards.

The Lectures on Chemistry are delivered daily during the five months of the Winter Session, commencing in November. The Lectures form a complete Course, and special Lectures on Technological Chemistry are given. Tutorial Class Examinations are held during the Session.

The Instructions in Analytical Chemistry are conducted in the Laboratories at Surgeons' Hall, which are open daily under the personal superintendence of Dr. Macadam, for the instruction of gentlemen in Chemical Analysis, and the prosecution of researches in Manipulative Chemistry.

The Preliminary Lectures in Practical Chemistry are also conducted in the Laboratories at Surgeons' Hall. The subjects selected for Examination are those with which Medical Students are specially called upon to exhibit a practical acquaintance.

Fees.—Lecture, £3 5s. (University Graduation, £4 4s.) Practical Chemistry (University, &c.), £3 3s.; Analytical Chemistry, £2 per month, £5 for three months, or £10 for six months.

UNIVERSITY OF GLASGOW.

Professor of Chemistry and Practical Chemistry.—Dr. Thomas Anderson, F.R.S.E.

ANDERSONIAN UNIVERSITY, GLASGOW.

Professor of Scientific Chemistry.—Dr. T. E. Thorpe.

GLASGOW MECHANICS' INSTITUTION.

Professor of Chemistry and Practical Chemistry.—Dr. R. Carter Moffat.

GLASGOW VETERINARY COLLEGE.

Professor of Chemistry.—Dr. R. Carter Moffat.

SCHOOL OF CHEMISTRY,

42, BATH STREET, GLASGOW.

Dr. Wallace. Mr. Tatlock, and Dr. Clark.

Scientific Course of Lectures on Inorganic and Organic Chemistry, by Dr. Clark. From 12 till 1 daily. Commencing Tuesday, November 4. Fee for the course, £2 2s. Laboratory Instruction in Analytical and Practical Chemistry, from 10 till 4 daily, Saturdays excepted. Commencing Tuesday, November 4. Fee for six months, exclusive of apparatus, £10 10s.

Evening Course of Laboratory Instruction in Analytical and Practical Chemistry. Tuesday and Thursday, from 7 p.m. till 9.30 p.m. Commencing November 4. Fee for one night per week, £1 1s. per quarter. Two nights per week, £2 2s. per quarter.

Evening Course of Lectures on Chemistry, in connection with the Practical Class, by Mr. Tatlock. Every Friday, from 8 p.m. till 9 p.m. Commencing November 7. Fee for the six months' course, 5s.

Spring Course of Practical Medical Chemistry, by Dr. Clark. Commencing Tuesday, January 6. Fee, £2 2s.

Summer Course of Practical Medical Chemistry, by Dr. Clark. Commencing Tuesday, May 4. Fee, £2 2s.

CHEMICAL LABORATORY AND CLASS ROOMS,
107, BATH STREET, GLASGOW.

Conducted by Dr. Milne.

The Laboratory is open daily from 10 till 4 (Saturdays excepted), for Instruction in Practical and Analytical Chemistry. Fee for six months, exclusive of apparatus, £10 10s. Fee for one month, £2 2s. Private Pupils (number limited to three) per month, £4 4s. Students can join the Laboratory at any time.

The Practical Evening Classes for Instruction in Analysis and Testing will meet on Tuesdays and Thursdays, from 7 p.m. till 9 p.m. Commencing November 4. Fee for one night per week, including apparatus and material, £1 1s. per quarter. Fee for two nights per week, £2 2s.

IRELAND.

DUBLIN.—TRINITY COLLEGE.

Professor of Chemistry.—Dr. Apjohn, F.R.S.

ROYAL COLLEGE OF SURGEONS, DUBLIN.

Professor of Chemistry.—Dr. Barker.

QUEEN'S COLLEGE, BELFAST.

Professor of Chemistry.—Dr. Andrews, F.R.S., &c.

QUEEN'S COLLEGE, GALWAY.

Professor of Chemistry.—Dr. T. H. Rowney.

A Laboratory for Practical Instruction is attached to all the Queen's Colleges. The usual Practical Course for the Medical Boards is given in the summer.

ROYAL COLLEGE OF SCIENCE FOR IRELAND,
STEPHEN'S GREEN, DUBLIN.

This College supplies, as far as practicable, a complete Course of Instruction in Science, applicable to the Industrial Arts. The subjects of Instruction are:—Pure and

Applied Mathematics, Descriptive Geometry and Mechanical Drawing, Mechanism, Theoretical and Applied Chemistry, Chemical Analysis, Physics, Botany, Zoology, Geology and Palæontology, Mineralogy, Mining, Machinery, Surveying, and Agriculture.

Professor of Theoretical Chemistry.—W. K. Sullivan, Ph.D., V.P.R.I.A.

Professor of Analytical and Applied Chemistry.—R. Galloway, F.C.S.

Assistant-Chemist.—W. Plunkett, F.C.S.

A Course of Lectures on Inorganic and Organic Chemistry is delivered by Dr. Sullivan three times a week during the Session. Fee for the entire course, £2.

A Course of Lectures on Technological Chemistry is delivered by Mr. Galloway twice a week during the Session. Fee for the course, £2.

The Chemical and Metallurgical Laboratories, under the direction of Mr. Galloway, are open every week day during the Session, except Saturday. Instruction is given in the different branches of Analytical Chemistry, including Assaying, and in the methods for performing Chemical research. Each Student is taught, not in class, but separately and independently; and he is supplied with a separate working table, with reagents, fuel, water, gas, and the larger and more expensive apparatus. Fee, for the Session of nine months, £12; or for three months, £5; or for one month, £2.

There are four Royal Scholarships, of the value of £50 each yearly, with free Education, including Laboratory Instruction, tenable for two years; two become vacant each year: they are given to Students who have been a year in the College. There are also nine Exhibitions attached to the College, of the yearly value of £50 each, with free Education, including Laboratory Instruction, tenable for three years; three become vacant each year. The Exhibitions are awarded at the annual May Examinations of the Science and Art Department.

A Diploma of Associate of the College is granted at the end of the three years' course.

The Session commences on Monday, October 6th.

ON THE

ACTION OF CHROMYL DICHLORIDE ON IODINE.

By R. W. EMERSON McIVOR, Glasgow.

In a paper communicated to the Literary and Philosophical Society of Manchester in November, 1866 (see CHEMICAL NEWS, vol. xx., p. 245), Dr. T. E. Thorpe announced the discovery of a new chromium oxychloride, obtained by heating chromyl dichloride, CrVO_2Cl_2 , in sealed tubes to about 185°C ., and maintaining it at that temperature for three or four hours, when it undergoes decomposition, the products being this new oxychloride and free chlorine. After having submitted this new compound to a careful study, Dr. Thorpe was induced to give it the formula $\text{ClCrVO}_2\text{O} \cdot \text{IVCr}''\text{O} \cdot \text{CrVO}_2\text{Cl}$, or—

and to regard it as the chromium term of a series of salts a few members of which had already been described by Peligot, viz.—

Potassium chlorochromate, $\text{K}_2\text{CrVO}_2\text{O} \cdot \text{O} \cdot \text{CrVO}_2\text{Cl}$
Sodium " $\text{Na}_2\text{CrVO}_2\text{O} \cdot \text{O} \cdot \text{CrVO}_2\text{Cl}$
Ammonium " $\text{NH}_4\text{CrVO}_2\text{O} \cdot \text{O} \cdot \text{CrVO}_2\text{Cl}$
Magnesium " $\text{MgCrVO}_2\text{O} \cdot \text{O} \cdot \text{CrVO}_2\text{Cl}$
Calcium " $\text{CaCrVO}_2\text{O} \cdot \text{O} \cdot \text{CrVO}_2\text{Cl}$

From some experiments which I recently made, I find that chromium chlorochromate, together with iodine monochloride, is formed by the action of chromyl di-

chloride, CrVO_2Cl_2 , prepared by heating a mixture of potassium dichromate, sodium chloride, and sulphuric acid, on dry iodine. When these two bodies are mixed in the proportions represented in the equation—

and the mixture warmed, chemical action is manifested by the production of a slight crackling noise, and the whole becoming converted into a black solid substance possessed of a very powerful chloroid smell. If the product of the action be transferred to a distillation-flask, and submitted to distillation, iodine monochloride passes over into the receiver. The then-remaining non-volatile portion is a black, brittle, amorphous, inodorous substance of a very hygroscopic nature. It is easily soluble in water, producing a dark brown-coloured solution, which smells of free chlorine. Carbon disulphide dissolves it but slightly. In strong hydrochloric acid it dissolves with a dark brown colouration, and, on boiling the solution, chlorine is evolved, the liquid becomes greenish yellow, and finally changes to the well-known green colour peculiar to an acid solution of chromic chloride. Upon boiling with dilute ammonium hydrate, chromic acid is dissolved, together with the whole of the chlorine, whilst chromate of chromium is precipitated as a greenish brown powder. When heated strongly in the air, it is resolved into chromic oxide, oxygen, and chlorine. It burns when heated in a stream of dry hydrogen gas, producing chromic oxide, water, and hydrochloric acid. Upon analysis it was found to be composed, in 100 parts, of—

Chlorine	21.58
Chromium	48.59
Oxygen (as difference) ..	29.83

100.00

The theoretical percentage composition of Dr. Thorpe's compound being—

Chlorine	21.86
Chromium	48.54
Oxygen	29.60

100.00

From the above considerations it is evident that the non-volatile residue consists of pure chromium chlorochromate.

ON THE ENERGIES OF THE IMPONDERABLES, WITH ESPECIAL REFERENCE TO THE MEASUREMENT AND UTILISATION OF THEM.*

By the Rev. ARTHUR RIGG, M.A.

(Continued from page 121.)

If the arms be held out horizontally, being raised direct from the sides, and not brought forward, they will be supported in that position by two muscles in each shoulder—or rather the portions of the two shoulder muscles which support them can be clearly defined and measured. The length of time for which this position can be maintained will, of course, vary considerably. The other evening I could hold mine in this position for only six minutes, that is to say, they became exhausted in this space of time. Therefore the sole power of the muscles employed was expended in maintaining the arm in that position for six minutes. Eight minutes will be found more near to the average.

Now let us consider what was happening whilst the arms were so held out. Clearly the muscles were giving off this note, that is to say, they are always giving it off when they are in action, and, therefore, the arm literally was swinging up and down, or vibrating, though to a very small and invisible extent. It would do so much more but for this peculiar arrangement; whilst the muscle contracts and produces the action that we usually call mus-

cular action, that contraction does not take place through the entire mass of muscle at the same time. Each fibre contracts, but not in the same portion of the muscle and at the same time; there are waves succeeding waves, and the consequence is that there is, to all appearance, a steadiness in the arms through the continuity of these waves. But, as regards the action, it is the same as though that wave passed along at once. Now, if the wave passed along at once then the arm would fall, because it would oscillate or move up and down as a wave does. Knowing how often that wave passes, you would know how often the arm fell. The arm falls 32 times per second. It falls as if it were perfectly free, and if perfectly free we can easily calculate the space through which it would have fallen in the 32nd part of a second, namely, the $\frac{1}{32}$ th of a foot; in other words, we have reached this stage, that the action of a muscle is such that it allows the arm to fall through the 64th part of a foot in the 32nd part of a second. Now let us get to another stage. The cause of its falling is the action of gravity upon the whole mass of the arm. You may remember that last Monday, in dealing with the pendulum, it was explained that in a compound pendulum different portions fell through different spaces, but that there is one point which we called O, termed the centre of oscillation, which may be regarded as representing the whole mass. Now, assuming a shoulder to be the point of suspension of the pendulum, it is the point O in the arm which would fall through the 64th part of a foot in the 32nd part of a second, and that point O, by a mathematical calculation, can always be found. Regarding the arm as a perfect cylinder, this point is at two-thirds of the length of the arm from the shoulder.

Again, the work done depends on the mass moved, or supported, and the mass moved is that which is calculated as at the centre of gravity, which for this purpose is about the elbow—about eleven inches from the shoulder. Therefore, assuming the arm to be 24 inches, then the point O at 16 inches from the shoulder, falls through the 64th part of a foot, in the 32nd part of a second, and it is very easy from that to ascertain how far the point at 11 inches from the shoulder, representing the whole weight of the arm, would fall in the same interval of time. We have, therefore, got the centre of gravity, the weight of the arm, and the distance it falls.* We consequently have all the elements wanted. We have the mass, the weight of the arm, the space (the $\frac{1}{32}$ th of the foot), and the time ($\frac{1}{32}$ nd of a second). Without going into the question of mathematics, the work done under these circumstances, as regards my own arm, was this, that I was able to do with both arms 1980 lbs. in the six minutes that elapsed before fatigue came on; in other words, the work done was the same as though I had lifted 1980 lbs. 1 foot high—1980 lbs. is very nearly 18 cwt. That is to say, the work that these two arms did in falling through that space, and being lifted back again, was very little short of a ton. If any one wants to know how much work the human arm is capable of doing when working on its own account, he may raise weights amounting to 9 cwt. on to a stool 1 foot high, and he would then ascertain the exact work that each arm did when left to support itself. Such is an outline of the mode in which the calculation is made. If there are any persons interested in it, as a question of actual calculation, a table on the wall may be of interest.†

* Dr. H. calls his and many other similar experiments "Statical," although reference is made to motion, because the muscles are kept in continued contraction until tired out, and undergo no translation in space, although a rapid and active molecular movement takes place within the muscles to which the work done is altogether due.

† To find the work done in holding arms horizontal, time before exhaustion being six minutes:—

From measurement, length of each arm is 24 inches.

From weighing, weight of each arm is 8 lbs.

From muscular note, vibration of each arm is 32 times per second.

From tables, centre of oscillation of each arm is 2.8ths of 24 inches, or 16 inches from shoulder.

From inspection, centre of gravity of each arm is 11 inches from shoulder.

* The Cantor Lectures, delivered before the Society of Arts.

The arm in this case was held steady, and doing what may be called static work, as distinguished from that which is dynamical or kinetic. Dr. Haughton took very great pains to ascertain the exact weight of these muscles in the shoulder. This was done thus:—There is a large muscle called the "deltoid" muscle; a portion only of this muscle is engaged in the work. After careful examination in various ways Dr. Haughton concluded that $\frac{1}{3}$ ths of this muscle is employed in the experiment. It would be out of place to enter into these details here; it may, however, be of general interest to place this investigation before you in a tabular form.

	Ozs. avoird.
Average weight of supraspinatus muscle ..	1671
Average of portion of deltoid	2830
	4501

Therefore 4.5 ozs. perform, on an average, 1206.5 ft.-lbs.
" 1 oz. performs 268 ft.-lbs. before being exhausted.

As this exhaustion is complete in 8.29 minutes, the average duration of endurance, 1 oz. in 1 minute does $\frac{268}{8.29} = 32.3$ ft.-lbs.

On one occasion these muscles were weighed and measured within 40 minutes after the execution of a criminal, so as to ascertain the exact size of them under circumstances where there had been no wasting from exhaustion. With the shoulder unloaded, the muscle was tired out in 8.29 minutes on an average of experiments. The weight of the muscles employed was 4½ ozs., and the work they did on an average was equivalent to the lifting of 1206 lbs. through a foot. The weight lifted through one foot for 1 ounce of muscle would be 32 lbs. He then put a weight of 2 lbs. in each hand, and held them out as before until fatigued, and he found the muscles were exhausted in 4 minutes, but the amount of work which each ounce of muscle did was 46 lbs., so that it did more work than it did before. Now, the power of the heart to send blood into the muscles, to keep up the action there, is not, in this case, equal to the action or work required from them; hence they began to fail in 4 minutes, whereas, in the other case, they kept at work for 8 minutes. In fact, the power exactly balanced the work in the 8 minutes; but it fell rather short, in 4 minutes. An experiment was tried in another form, namely, hanging a weight on the wrist and keeping the elbow close to the side, a different muscle (biceps) came into play. This muscle weighs about 8 ozs.; the power lasted 9¼ minutes, and the weight, per ounce of muscle, lifted was 41.

Now, coming to dynamical work, when the muscles are engaged in producing motion, the muscles of the trunk of the body are employed simply in supplying the other muscles with that upon which they live during the time they are at work; they do no external work themselves. This was alluded to in an early part of the lecture, when told that there are certain muscles which

Now from the usual expression—

$$S = \frac{1}{2} G T^2$$

$$\text{In this case } S = \frac{1}{2} 32 \left(\frac{1}{32} \right)^2$$

$$= \frac{1}{64} \text{ foot.}$$

Therefore centre of oscillation falls through $\frac{1}{64}$ ft. in $\frac{1}{32}$ of a second,

or " " " $\frac{60 \cdot 32}{64}$ i.e., 30 feet in one minute.

If at 16 inches from the shoulder there is a fall of 30 feet per minute, then at 11 inches from the shoulder there is a fall of $\frac{11 \cdot 30}{16}$ feet per minute.

Therefore the work done by one arm is $\frac{8 \cdot 11 \cdot 30}{16}$ ft.-lbs. per minute.

Therefore "total work" by both arms before exhaustion is 165.62 ft.-lbs., or 1980 ft.-lbs., that is nearly 18 cwt. lifted through one foot in six minutes.

act involuntarily; for example, if the heart cannot propel blood as fast as the muscle needs it, and if the will insists upon that muscle doing further work, then the heart is called upon to do what it cannot do, and death ensues. The two must be harmonised; and where this harmony is broken, as sometimes happens, in a boat-race, and other cases of violent exertion, accident or death results.

STATIC WORK DONE BY MUSCLES.

Muscles used.	Work in foot-pounds.	Duration of labour, in minutes.	Weight of muscles in ounces avoird.	Rate of work in foot-lbs. per oz. per min
Unloaded muscles of shoulder ..	1206	8.29	4.50	32.3
Loaded muscles of shoulder ..	842	4.05	4.50	46.2
Loaded muscles of forearm ..	3170	9.29	8.21	41.5

DYNAMICAL WORK DONE BY MUSCLES OF THE WHOLE BODY.

Kind of Work.	Quantity of work in foot-pounds.	Duration of labour, in minutes.	Weight of muscles in oz. avoird.	Rate of work in lbs. per oz. per minute.
Boat race ..	61,040	7	575	15.17
Barrow lift ..	2,038,400	480	575	7.39
Running with load ..	10,091	0.55	575	35.11
Day labour ..	792,400	600	575	2.30

This table shows the results of experiments on different kinds of work. First, there is the case of a boat race which was rowed in seven minutes. The whole weight of the muscles employed in actually doing the work, viz., those in the arms and legs, was 575 ozs.; the work done, making all allowances for the weight of the boat and the people in it, &c., was equivalent to 60,040 lbs. raised through a foot, giving an average of only 15 lbs. per ounce per minute, so that the contrast is very great between static work and dynamical work, the former being three times as great. Next comes an instance bringing into play all the active muscles of the body. It was a plan adopted in some railway works, raising rubble from a great depth. There was a pulley at the top of a shaft, over which passed a rope, and a stage at each side large enough to carry a barrow. One barrow was filled at the bottom, then a man stepped into the empty barrow at the top, and his weight in falling to the bottom of the shaft lifted the barrow full of earth. He then ran up a ladder to the top, and was ready to descend again. By that means his own weight lifted up the full barrow of earth. With work like that a man worked for 480 minutes, and he did two millions of units of work. Compared with the boat race he was only half as industrious, and the length of time was very much greater, but he only did 7.39 foot-lbs. per oz. per minute. In the next case a man ran with a load upon his shoulders, and his muscular power was knocked up in half a minute, but the work he did was 35 foot-lbs. per minute, approaching very nearly the static work. Last comes a day labourer, who generally takes it very easy, and it appears he only does 2 foot-lbs. per oz. per minute, so that if he complains of getting small pay he does little work for it; it must be remembered, however, that he works for 10 hours a day at it.

Time warns me to close. It may, however, be of interest to state that, calculated as machinery would be calculated, the heart receives and propels the whole amount of blood in the human body in 42 seconds.

To those who care for the subject of this evening's lecture, and have not altogether laid aside their mathematical knowledge, the information in Dr. Haughton's book will prove both instructive and interesting. To follow up the investigation, they may study the action of a horse in walking and drawing a load, also the construction of carriages, so that the animal may most easily raise a

loaded cart over an obstacle on the road, and, further, decide upon the inclination of the traces to the roadway. These being done, the investigator will find much scope for original work in examining the various ways in which horses are harnessed so as to utilise their vital energies. This done, boats and bicycles, as means of utilising muscular energy, are worthy of thought. Perplexity and confusion seem to be stamped upon modern usages in these matters, and the conclusion is forced upon us that the utilisation of the vital energies has not yet been reduced to a system.

(To be continued).

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Under this heading will be found an encyclopaedic list of chemical papers published abroad during the past week, with abstracts of all susceptible of advantageous abridgment. The two half-yearly volumes of the CHEMICAL NEWS, with their copious indices, will, therefore, be equivalent to an English edition of the "Jahresberichte."

NOTE. All degrees of temperature are Centigrade, unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances de l'Académie des Sciences, August 18, 1873.

Fourth Notice on Guano.—M. Chevreul.—The author gives a description of a crystalline matter extracted by cold water from the guano, and of another complex substance insoluble in cold water. It contains a considerable amount of avic acid, but does not give off the odour of this body until treated with alcohol. "Lastly, in the residue of the guano, after exhaustion with cold water, boiling alcohol, and boiling water, there remains phosphate of lime in a particular state, to which I shall return in a final notice, where I shall show how my experiments throw a new light upon the part played by guano in agriculture, and how it realises in practice all the theoretical views which I have made known thirty years ago on the conception of a typical manure."

Ammoni-Nitrometry; a new System for Determining Ammonia and Nitrogen in Organic Compounds, and Nitric Acid in Natural Waters, Soils, and Manures.—M. Piuggari.—The most important data to be determined in all these cases are ammonia, free and combined, nitrogen existing in organic matters, and nitric acid or nitre derived from the oxidation of such matters. The general means to be employed are oxidation and reduction; but as all the agents employed hitherto are neither energetic nor pure enough to give results sufficiently exact, the author adopts, at once as oxidising and as reducing agent for organic matters, a mixture of chloride of silver, moist and recently precipitated, and of very pure hydrate of potassa. These substances, which are very energetic, and which may be obtained quite free from ammonia, are allowed to act for two or three hours at a temperature of 55° to 60°. By this action all the nitrogen of the organic matters is transformed into ammonia, nitrous, and nitric acid; the two latter of which are then transformed into ammonia by reducing agents. The reducing agent which the author employs in this case—as in all those where it is required to reduce and determine nitrous compounds—is nascent hydrogen produced by aluminium filings, and a pure alkaline hydrate at a temperature which ought not to exceed that of boiling water. The process is continued for half-an-hour to an hour according to the amount of the matter to be reduced, and the ammonia is then distilled off. The author has convinced himself of the complete reduction by this process of organic matters and nitrous compounds by experimenting with types of known

composition, such as morphia, codeia, strychnia, albumin, gelatin, and uric acid. The amount of albumen obtained has been in accordance with theory, with a difference of at most 1 to 3 per cent, due doubtless to the very small quantities operated upon—0.0005 grm. to 0.0002 grm. per half litre of water. The ammonia distilled over is determined by Nessler's test if the quantities are very small. If they exceed $\frac{1}{100}$ th of a milligram of ammonia per cubic centimetre, the determination is effected by means of a special reagent, founded on the reaction of 1 or 2 drops of phenol, and 5 to 6 c.c. of hypochlorite of soda added to the liquid to be tested. This reagent gives with the distilled ammoniacal liquid a fine blue violet colouration, soluble and very stable; the intensity of which may be compared with a normal liquor by means of Collardeau's colorimeter.

Hydrochlorate of Tereben, and the Isomerism of the Compounds of the Formula $C_{10}H_{16}HCl$.—M. J. Ribau.—The hydrochlorate of tereben is completely without action upon polarised light; it forms crystals of a camphor-like odour, and recalls in certain respects the hydrochlorates of terebenthen and camphen. Its composition is:—

Carbon	69.58
Hydrogen	9.85
Chlorine	20.57

100.00

It melts at 125°, and is quickly decomposed by water, which removes the bulk of the hydrochloric acid, converting the substance into a mixture of a crystalline carbide, $C_{10}H_{16}$, which the author calls β -camphen, and of undecomposed hydrochlorate. The hydrochlorate dissolves in hot absolute alcohol; and if the temperature of 55° to 60° is not exceeded the bulk of the product is deposited in fine transparent laminae, not containing more than 17 to 18 per cent of chlorine. The author concludes that the hydrochlorate of terebenthen is undecomposable by cold water, and yields only traces of hydrochloric acid at 100°. The hydrochlorates of camphen are slowly decomposed by cold water, and by the same liquid at the boiling-point; the primitive crystalline camphen being regenerated. The hydrochloric ethers of the two borneols experience an analogous decomposition under the same circumstances, but with less intensity. The hydrochlorate of tereben is dissociated at ordinary temperatures; it is decomposed most rapidly by the action of cold water, and under the same influence at 100° furnishes only liquid compounds, contrary to what has been observed with the liquid combinations of the camphens and the borneols.

Direct Demonstration of the Fundamental Principles of Thermo-Dynamics.—(Continued.)—M. Ledieu.—This treats of the fundamental relation between the quantity of heat applied to a body, the change of temperature, and the variation and duration of the vibrations.

Letter from M. Nordenskjöld on Carbonaceous Dust, with Metallic Iron, observed in Snow (Dated from Mossel Bay, lat. 79° 53' N.; Received at Tromsøe, July 24).—The writer remarks that in December, 1871, he found in some snow collected towards the end of a five or six days continuous fall in Stockholm a large quantity of dark powder like soot, and consisting of an organic substance rich in carbon. It was like the meteoric dust which fell with meteorites at Hesse near Upsal in Jan., 1869. It contained also small particles of metallic iron. Suspecting the railways and houses of Stockholm might have furnished these matters, he got his brother, who lived in a desert district in Finland, to make similar experiments; which he did, and obtained a similar powder. In his Arctic voyage the writer has met with like phenomena. The snow from floating ice has furnished on fusion a greyish residue consisting mostly of diatoms (whole or injured); but the black specks, a quarter of a millimetre in size, contained metallic iron covered with oxide of iron, and probably also carbon.

He thinks, therefore, that snow and rain convey cosmic dust to the earth, and invites further observation on the subject. M. Daubree, in presenting the letter, recalled a case of meteoric dust having fallen at Orgueil in 1864. He expressed the hope that M. Nordenskjöld has obtained sufficient quantities of pulverulent matter to be able to determine a characteristic fact—the presence or absence of nickel.

The Cryptograph of M. Pelegrin.—M. Dupuy de Lôme.—The cryptograph is described as an instrument designed to be raised on the ground, and to convert into expressions capable of being transmitted directly and secretly by telegraph, the polar co-ordinates of points which determine a given figure; whence the possibility with this instrument of following and interpreting, that is, of drawing, in Paris, e.g., what correspondents in different parts of the country in telegraphic communication with Paris may see and telegraph but do not interpret.

Experimental Researches on Explosive Matters.—MM. Roux and Larran.—The authors formerly determined the heat of combustion of five kinds of powder made in France. They here determine for these powders the volume of the gaseous products of combustion reduced to zero and 0.76 m. Their tables also give the numbers expressing heat of combustion; the pressure of the permanent gases of 1 kilo. of powder, having at the temperature T of the flame a volume equal 1 litre; and the maximum work produced by indefinite expansion of the gases of 1 kilo. Some other substances, as gun-cotton, dynamite, were also experimented with.

Variations of Hæmoglobin in the Zoological Series.—M. Quinquaud.—The progressive diminution of quantity of hæmoglobin in the same volume of blood generally follows the animal scale; but primates have not most hæmoglobin. Young animals have less than adults. From about 25 to 50 years in man the proportion is pretty constant; thereafter it diminishes. Birds have much less hæmoglobin than mammals. Females have less than males. The lymph of crustacea has 4 to 5 c.c. of oxygen per cent, while ordinary water, at its maximum of saturation in winter, contains only 1 c.c. per cent; and in summer, $\frac{1}{2}$ c.c. M. Quinquaud gives a list of animals, with the proportion of hæmoglobin in each.

Former Existence during the Quaternary Period of a Large Glacier in the Mountains of Aubrac (Lozère).—M. G. Faber.

Three Short Notes on Falling Stars.—MM. Dufour, Tisserand, and Chapeler respectively.

Les Mondes, Revue Hebdomadaire des Sciences, par L'Abbé Moigno, Tome xxxi., No. 18, August 28, 1873.

Relation between the Atomic Weight, the Specific Gravity, and the Hardness of the Metallic Elements.—S. Bottone.—The author holds that the hardness of any metallic element has for its natural measure the quotient or ratio of the specific gravity divided by the atomic weight. The theoretical results thus obtained agree closely with the hardness determined experimentally by causing a cylinder of steel to penetrate to a constant depth into the metal in question by means of a determinate rotatory movement.

MISCELLANEOUS.

The Adulteration Act.—Mr. Alfred G. Anderson has been elected Analyst to the Vestry of St. Martin-in-the-Fields, London.

Birkbeck Literary and Scientific Institution.—This Institution has just issued its prospectus for the winter session. Evening classes for ladies and gentlemen have been arranged in all branches of education, and a class is announced for the preparation of candidates for the Civil

Service Open Competitions. Professor Fawcett, M.P., has kindly consented to deliver an address in commemoration of the opening of the fiftieth session. During the vacation the interior of the lecture theatre has been entirely reconstructed. The list of lectures contains the names of several of the most popular occupants of the platform. Important additions have been made to the library, and the reading room is well supplied with current literature.

British Association for the Advancement of SCIENCE.

The Forty-third ANNUAL MEETING of this Association will be held in BRADFORD, commencing on WEDNESDAY, September 17, 1873.

President Designate:

Professor A. W. WILLIAMSON, Ph.D., F.R.S., F.C.S.

Election of Members and Associates.

The Executive Committee at Bradford will elect New Members and Associates, on the following conditions:—

- I. New Life Members for a composition of £10, which entitles them to receive gratuitously the Reports of the Association which may be published after the date of payment.
- II. New Annual Subscribers for a payment of £2 for the first year. They receive gratuitously the Reports for the year of their admission and for every following year in which they continue to pay a Subscription of £1 without intermission.
- III. Associates for this Meeting only for a payment of £1. They are entitled to receive the Report of the Meeting at two-thirds of the publication price. Associates are not eligible to serve on Committees or to hold any office.

Ladies may become Members or Associates on the same terms as Gentlemen. Ladies' Tickets (*transferable to Ladies only*) may be obtained on payment of £1. Cheques and Post-Office Orders to be made payable to Alfred Harris, Jun., Esq., Bradford.

After September 13, personal application for Tickets must be made at the Reception Room, Bradford, which will be opened on Monday, September 15, at 1 p.m.

General and Evening Meetings in St. George's Hall.

The First General Meeting will be held on Wednesday, September 17, at 8 p.m. precisely, when Dr. CARPENTER, LL.D., F.R.S., &c., will resign the Chair, and the President Elect will assume the Presidency, and deliver an Address. On Thursday, Evening, September 18, at 8 p.m., a Soirée; on Friday Evening, September 19, at 8.30 p.m., a Discourse by Professor W. C. Williamson, F.R.S., of Manchester, on Coal and Coal Plants; on Saturday Evening, September 20, a Lecture on Fuel, to Working Men only, by Mr. Siemens, F.R.S.; on Monday Evening, September 22, at 8.30 p.m., a Discourse on Molecules, by Professor Clerk Maxwell, F.R.S.; on Tuesday Evening, September 23, at 8 p.m., a Soirée; on Wednesday, September 24, the concluding General Meeting will be held at 2.30 p.m., and in the Evening a Grand Concert will be given in St. George's Hall, at 8 p.m.

EXCURSIONS on Thursday, the 25th September, to the following places of interest have been arranged:—Harrogate, Ripon, Studley, Bolton Abbey, Gordale Scar, Malham, Clapham Caves, Settle Caves, and Ingleboro'.

Lists and Prices of Lodgings, and other general information will be given, on application at the Local Secretaries' Office, Bradford.

The names of New LIFE MEMBERS, ANNUAL SUBSCRIBERS, and ASSOCIATES for this Meeting only, are now being received and Tickets issued at the Offices of the Association, Market Street; also Tickets for Ladies who do not desire to become Members or Associates: these are *transferable to Ladies only*.

JAMES R. CAMPBELL, D.D., Hon.
RICHARD GODDARD, Local
PEILE THOMPSON, Secretaries.

North London School of Chemistry, Pharmacy, &c. Established 12 years.—Conducted by Mr. J. C. BRAITHWAITE, for thirteen years Principal Instructor in the Laboratories of the Pharmaceutical Society of Great Britain, and Demonstrator of Practical Pharmacy, Pharmaceutical Latin, &c.

The Session 1873-1874 commences on the 1st of October, when the LABORATORY will be open for Instruction in Practical Chemistry as applied to Pharmacy, Medicine, Analysis, &c. Terms moderate.

THE CLASSES for CHEMISTRY, MATERIA MEDICA, BOTANY, and LATIN, meet as usual at 8 p.m.

Fee to either Class Half-a-Guinea per Month. Pupils desirous of doing so can attend until qualified for one inclusive Fee.

The BOTANICAL GARDEN affords every facility to Students desirous of acquiring a Practical Knowledge of Botany. During the Season BOTANICAL EXCURSIONS are made every Saturday at 10 a.m.

As each Pupil works independently, he can enter at any period to either Classes or Laboratory.

All Fees must be paid in advance.

PRIVATE TUITION for the Preliminary Modified Minor and Major Examinations, &c.

A few Pupils received to Board in the house.

Applications, accompanied with a stamped envelope, addressed to—
34, KENTISH TOWN ROAD, N.W.

THE CHEMICAL NEWS.

NO. XXVIII. No. 721.
20 SEP 73

BRITISH ASSOCIATION
FOR THE
ADVANCEMENT OF SCIENCE.

BRADFORD MEETING, SEPTEMBER 17, 1873.

INAUGURAL ADDRESS OF THE PRESIDENT,
ALEXANDER W. WILLIAMSON, PH.D., F.R.S., F.C.S.

LADIES AND GENTLEMEN,—

INSTEAD of rising to address you on this occasion, I had hoped to sit quietly amongst you, and to enjoy the intellectual treat of listening to the words of a man of whom England may well be proud—a man whose life has been spent in reading the great book of nature, for the purpose of enriching his fellow men with a knowledge of its truths—a man whose name is known and honoured in every corner of this planet to which a knowledge of science has penetrated—and, let me add, a man whose name will live in the grateful memory of mankind as long as the records of such noble work are preserved.

At the last Meeting of the British Association I had the pleasure of proposing that Dr. Joule be elected President for the Bradford Meeting, and our Council succeeded in overcoming his reluctance and in persuading him to accept that office.

Nobly would Joule have discharged the duties of President had his bodily health been equal to the task; but it became apparent after a while that he could not rely upon sufficient strength to justify him in performing the duties of the chair, and, in obedience to the orders of his physician, he placed his resignation in the hands of the Council about two months ago. When, under these circumstances, the Council did me the great honour of asking me to accept their nomination to the Presidency, I felt that their request ought to have with me the weight of a command.

For a good many years past Chemistry has been growing at a more and more rapid rate, growing in the number and variety of facts which are added to its domain, and not less remarkably in the clearness and consistency of the ideas by which these facts are explained and systematised. The current literature of chemical research extends each year to the dimensions of a small library; and mere brief abstracts of the original papers published annually by the Chemical Society, partly aided by a grant from this Association, take up the chief part of a very stout volume. I could not, if I would, give you to-night even an outline of the chief newly discovered compounds and of the various changes which they undergo, describing each of them by its own name (often a very long one) and recording the specific properties which give to each substance its highest scientific interest. But I am sure that you would not wish me to do so if I could; for we do not meet here to study chemistry; I conceive that we meet here for the purpose of considering what this wondrous activity in our science means, what is the use of it, and, true to our object as embodied in the name of this Association, to consider what we can do to promote the Advancement of Science. I propose to lay before you some facts bearing on each of these questions, and to submit to you some considerations respecting them.

In order to ascertain the meaning of the work which has been going on in chemistry, it will, I think, be desirable for us to consider the leading ideas which have

been in the minds of chemists, and which guided their operations.

Now, since the father of modern chemistry, the great Dalton, gave to chemists a firm hold of the idea of Atoms, their labours have been continually guided by that fundamental idea, and have confirmed it by a knowledge of more and more facts, while at the same time steadily adding to our knowledge of the properties of atoms. Every chemist who is investigating a new compound takes for granted that it must consist of a great number of atom-clusters (called by him molecules), all of them alike, and each molecule consisting of a certain number of atoms of at least two kinds. One of his first endeavours is to ascertain how many atoms of each kind there are in each molecule of the compound. I must not attempt to describe to you the various kinds of experiment which he performs for the purpose of getting this information, how each experiment is carried out with the aid of delicate instruments and ingenious contrivances found by long experience to enable him to obtain the most trustworthy and accurate results; but I want to draw your attention to the reasoning by which he judges of the value of such experiments when they agree among themselves, and to the meaning which he attaches to their result.

If the result of his experiments does not nearly agree with any atomic formula (that is, if no conceivable cluster of atoms of the kinds known to be in the compound would on analysis give such results as those obtained), the chemist feels sure that his experiments must have been faulty: either the sample of substance which he worked upon contained foreign matter, or his analyses were not made with due care. He sets to work again, and goes on till he arrives at a result which is consistent with his knowledge of the combining properties of atoms. It is hardly necessary to say that even the best experiment is liable to error, and that even a result obtained with the utmost care cannot be expected to afford more than an approximation to the truth. Every good analysis of a pure compound leads to results which approximate to those required by the Atomic Theory; and chemists trust so thoroughly to the truth of that guide, that they correct the results of such analysis by the aid of it.

The chemical idea of atoms serves for two purposes:—

- (1). It gives a clear and consistent explanation of an immense number of facts discovered by experiment, and enables us to compare them with one another and to classify them.
- (2). It leads to the anticipation of new facts, by suggesting new compounds which may be made; at the same time it teaches us that no compounds can exist with their constituents in any other than atomic proportions, and that experiments which imply the existence of any such compound are faulty.

We have the testimony of the great Berzelius to the flood of light which the idea of atoms at once threw on the facts respecting combining proportions which had been accumulated before it was made known; and from that time forward its value has rapidly increased as each succeeding year augmented the number of facts which it explained.

Allow me at this point of my narrative to pause for a moment in order to pay a tribute of respect and gratitude to the memory of one who has recently passed from among us, and who in the time of his full activity was a leader of the discoveries of new facts in the most difficult part of our science. Liebig has been generally known in this country through his writings on agricultural chemistry, through his justly popular letters on chemistry, and other writings, by means of which his brilliant intellect and ardent imagination stimulated men to think and to work. Among chemists he was famed for his numerous discoveries of new organic compounds, and their investigation by the aid of improved methods; but I believe that the greatest service which his genius rendered to science was the establishment of the chemical school of Giessen, the prototype of the numerous chemical schools for which

Germany is now so justly celebrated. I think it is not too much to say that the Giessen laboratory, as it existed some thirty years ago, was the most efficient organisation for the promotion of chemistry which had ever existed.

Picture to yourselves a little community of which each member was fired with enthusiasm for learning by the genius of the great master, and of which the best energies were concentrated on the one object of experimental investigation.

The students were for the most part men who had gone through a full curriculum of ordinary studies at some other university, and who were attracted from various parts of the world by the fame of this school of research.

Most of the leading workers of the next generation were pupils of Liebig; and many of them have established similar schools of research.

We must not, however, overlook the fact that Liebig's genius and enthusiasm would have been powerless in doing this admirable work, had not the rulers of his Grand Duchy been enlightened enough to know that it was their duty to supply him with the material aids requisite for its successful accomplishment.

Numberless new compounds have been discovered under the guidance of the idea of atoms; and in proportion as our knowledge of substances and of their properties became more extensive, and our view of their characteristics more accurate and general, were we able to perceive the outlines of their natural arrangement, and to recognise the distinctive characteristics of various classes of substances. I wish I could have the pleasure of describing to you the origin and nature of some of these admirable discoveries, such as homologous series, types, radicals, &c.; but it is more to our purpose to consider the effect which they have had upon the idea of atoms, an idea which, still in its infancy, was plunged into the intellectual turmoil arising from a variety of novel and original theories suggested respectively by independent workers as best suited for the explanation of the particular phenomena to which their attention was mainly directed.

Each of these workers was inclined to attach quite sufficient importance to his own new idea, and to sacrifice for its sake any other one capable of interfering with its due development.

The father of the atomic theory was no more; and the little infant had no chance of life, unless from its own sterling merits it were found useful in the work still going on.

What then was the result? Did it perish like an ephemeral creation of human fancy? or did it survive and gain strength by the inquiries of those who questioned Nature and knew how to read her answers?

Although anticipating my answer to these questions, you will probably be surprised to hear the actual result which I have to record, a result so wonderful that the more I think of it the more I marvel at it. Not only did these various theories contain nothing at variance with the atomic theory; they were found to be natural and necessary developments of it, and to serve for its application to a variety of phenomena which were unknown to its founder.

Among the improvements of our knowledge of atoms which have taken place, I ought to mention the better evaluations of the relative weight of atoms of different kinds, which have been made since Dalton's time. More accurate experiments than those which were then on record have shown us that certain atoms are a little heavier or lighter than was then believed, and the work of perfecting our observations is constantly going on with the aid of better instruments and methods of operation. But, apart from these special corrections, a more sweeping change has taken place, not in consequence of more accurate experiments interpreted in the usual way, but in consequence of a more comprehensive view of the best experimental results which had been obtained, and a more consistent interpretation of them. Thus the atomic weight of carbon had been fixed at 6 by

Dumas's admirable experiments; and it was quite conceivable that a still more perfect determination might slightly increase or diminish this number. But those who introduced the more sweeping change asserted in substance that two of these supposed atoms, whatever may be the precise weight of each, always are together and never separate from one another; and they accordingly applied the term atom to that indivisible mass of carbon weighing twice as much as a carbon atom had been supposed to weigh. So also with regard to other elements, it has been shown that many atoms are really twice as heavy as had been supposed, according to the original interpretation of the best experiments. This change was brought about by what I may be permitted to call the operation of stock-taking. Dalton first took stock of our quantitative facts in a business-like manner; but the amount and variety of our chemical stock increased so enormously after his time, that the second stock-taking absorbed the labours of several men for a good many years. They were men of different countries and very various turns of mind; but, as I mentioned just now, they found no other fundamental idea to work with than Dalton's; and the result of their labours has been to confirm the truth of that idea and to extend greatly its application.

One of the results of our endeavours to classify substances according to their natural resemblances has been the discovery of distinct family relationships among atoms, each family being distinguished by definite characteristics. Now, among the properties which thus characterise particular families of atoms, there is one of which the knowledge gradually worked out by the labours of an immense number of investigators must be admitted to constitute one of the most important additions ever made to our knowledge of these little masses.

I will endeavour to explain it to you by a simple example. An atom of chlorine is able to combine with 1 atom of hydrogen or 1 atom of potassium; but it cannot combine with 2 atoms. An atom of oxygen, on the other hand, can combine with 2 atoms of hydrogen or with 2 atoms of potassium, or with 1 atom of hydrogen and 1 of potassium; but we cannot get it in combination with 1 atom of hydrogen or of potassium solely.

Again, an atom of nitrogen is known in combination with 3 atoms of hydrogen; while an atom of carbon combines with 4 of hydrogen. Other atoms are classified, from their resemblance to these respectively, as Monads, Dyads, Triads, Tetrads, &c.

The combining value which we thus recognise in the atoms of these several classes has led us naturally to a consideration of the order in which atoms are arranged in a molecule. Thus, in the compound of oxygen with hydrogen and potassium, each of these latter atoms is directly combined with the oxygen, and the atom of oxygen serves as a connecting link between them. Hydrogen and potassium have never been found capable of uniting directly with one another; but when both combined with 1 atom of oxygen they are in what may be called indirect combination with one another through the medium of that oxygen.

One of the great difficulties of chemistry some few years ago was to explain the constitution of isomeric compounds, those compounds whose molecules contain atoms of like kinds and in equal numbers, but which differ from one another in their properties. Thus a molecule of common ether contains 4 atoms of carbon, 10 atoms of hydrogen, and 1 of oxygen. Butylic alcohol, a very different substance, has precisely the same composition. We now know that in the former the atom of oxygen is in the middle of a chain of carbon atoms, whereas in the latter it is at one end of that chain. You might fancy it impossible to decide upon anything like consistent evidence such questions as this; but I can assure you that the atomic theory, as now used by chemists, leads frequently to conclusions of this kind, which are confirmed by independent observers, and command general assent.

That these conclusions are, as far as they go, true descriptions of natural phenomena is shown by the fact that each of them serves in its turn as a stepping-stone to further discoveries.

One other extension of our knowledge of atoms I must briefly mention, one which has as yet received but little attention, yet which will, I venture to think, be found serviceable in the study of the forces which bring about chemical change.

The original view of the constitution of molecules was statical; and chemists only took cognizance of those changes of place among their atoms which result in the disappearance of the molecules employed, and the appearance of new molecules formed by their reaction on one another. Thus, when a solution of common salt (sodic chloride) is mixed with a solution of silver nitrate, it is well known that the metallic atoms in these respective compounds change places with one another, forming silver chloride and sodic nitrate; for the silver chloride soon settles to the bottom of the solution in the form of an insoluble powder, while the other product remains dissolved in the liquid. But as long as the solution of salt remained undecomposed, each little molecule in it was supposed to be chemically at rest. A particular atom of sodium which was combined with an atom of chlorine was supposed to remain steadily fixed to it. When this inactive solution was mixed with the similarly inactive solution of silver nitrate, the interchange of atoms known to take place between their respective molecules was nominally explained by the force of predisposing affinity. It was, in fact, supposed that the properties of the new compounds existed and produced effects before the compounds themselves had been formed.

I had occasion to point out a good many years ago that molecules which appear to be chemically at rest are reacting on one another when in suitable conditions, in the same kind of way as those which are manifestly in a state of chemical change—that, for instance, the molecules of liquid sodic chloride exchange sodium atoms with one another, forming new molecules of the same compound undistinguishable from the first, so that, in an aggregate of like molecules, the apparent atomic rest is the result of the interchange of like atoms between contiguous molecules.

Such exchanges of atoms take place not only between molecules of identical composition, but also between contiguous molecules containing different elements. For instance, in a mixture of sodic chloride and potassic iodide an interchange of metallic atoms takes place, forming potassic chloride and sodic iodide. The result of the exchange in such a case is to form a couple of new molecules different from the original couple. But these products are subject to the same general law of atomic exchanges, and their action on one another reproduces a couple of molecules of the materials.

Thus a liquid mixture formed from two compounds, contains molecules of four kinds, which we may describe as the two materials and the two products. The materials are reacting on one another, forming the products; and these products are, in their turn, reacting on one another, reproducing the materials.

If one of the products of atomic exchange between two molecules is a solid while the other remains liquid (as when sodic chloride is mixed with silver nitrate), or if one is gaseous while the other remains liquid, so that the molecules of the one kind cannot react on those of the other kind and reproduce the materials, then the continued reaction of the materials on one another leads to their complete mutual decomposition. Such complete mutual decomposition of two salts take place whenever they react on one another under such conditions that the products cannot react on one another and reproduce the materials; whereas partial decomposition takes place whenever the materials form a homogeneous mixture with the products.

Now, if in any such homogeneous mixture more ex-

changes of atoms take place between the materials than between the products, the number of molecules of the products is increased, because more of them are being made than unmade; and reciprocally, if more exchanges of atoms take place between the products than between the materials, the number of molecules of the materials is increased. The mixture remains of constant composition when there are in the unit of time as many decomposing changes as reproducing changes.

Suppose that we were to determine by experiment the proportion between the number of molecules of the materials, and the number of molecules of the products, in a mixture the composition of which remains constant, and that we found, for instance, twice as many of materials as of products; what would this mean? Why, if every two couples of materials only effect in the unit of time as many exchanges as every one couple of products, every couple of materials is only exchanging half as fast as every couple of products.

In fact you perceive that a determination of the proportion in which the substances are present in such a mixture will give us a measure of the relative velocities of those particular atomic motions; and we may thus express our result:—The force of chemical combination is inversely proportional to the number of atomic interchanges.

I cannot quit this part of our subject without alluding to the fact that some few chemists of such eminence as to be entitled to the most respectful attention, have of late years expressed an opinion that the idea of atoms is not necessary for the explanation of the changes in the chemical constitution of matter, and have sought as far as possible to exclude from their language any allusion to atoms.

It would be out of place on this occasion to enter into any discussion of the questions thus raised; but I think it right to point out:—

I. That these objectors have not shown us any inconsistency in the atomic theory, nor in the conclusions to which it leads.

II. That neither these nor any other philosophers have been able to explain the facts of chemistry on the assumption that there are no atoms, but that matter is infinitely divisible.

III. That when they interpret their analyses, these chemists allow themselves neither more nor less latitude than the Atomic Theory allows; in fact they are unconsciously guided by it.

These facts need no comment from me.

Our science grows by the acquisition of new facts which have an intelligible place among our ideas of the order of nature; but in proportion as more and more facts are arranged before us in their natural order, in proportion as our view of the order of nature becomes clearer and broader, we are able to observe and describe that order more fully and more accurately—in fact, to improve our ideas of the order of nature. These more extensive and more accurate ideas suggest new observations, and lead to the discovery of truths which would have found no place in the narrower and less accurate system. Take away from Chemistry the ideas which connect and explain the multifarious facts observed, and it is no longer a science; it is nothing more than a confused and useless heap of materials.

The answer to our question respecting the meaning of the earnest work which is going on in our science must, I think, now be plain to you. Chemists are examining the combining-properties of atoms, and getting clear ideas of the constitution of matter.

Admitting, then, for the present, that such is the meaning of chemical work, we have to consider the more important question of its use; and I think you will agree with me that, in order to judge soundly whether and in what manner such a pursuit is useful, we have to consider its effect upon Man. What habits of mind does it engender? What powers does it develop? Does it develop good and noble qualities and aspirations, and

to make men more able and more anxious to do good to their fellow men? Or is it a mere idle amusement, bearing no permanent fruits of improvement?

You will, I think, answer these questions yourselves if I can succeed in describing to you some of the chief qualities which experience has shown to be requisite for the successful pursuit of Chemistry, and which are necessarily cultivated by those who qualify themselves for such a career.

One of the first requirements on the part of an investigator is accuracy in observing the phenomena with which he deals. He must not only see the precise particulars of a process as they present themselves to his observation; he must also observe the order in which these particular appearances present themselves under the conditions of each experiment. No less essential is accuracy of memory. An experimental inquirer must remember accurately a number of facts; and he needs to remember their mutual relations, so that one of them when present to his mind may recall those others which ought to be considered with it. In fact he cultivates the habit of remembering facts mainly by their place in Nature. Accuracy in manual operations is required in all experimental inquiries; and many of them afford scope for very considerable skill and dexterity.

These elementary qualities are well known to be requisite for success in experimental science, and to be developed by careful practice of its methods; but some higher qualities are quite as necessary as these in all but the most rudimentary manipulations, and are developed in a remarkable degree by the higher work of science.

Thus it is of importance to notice that a singularly good training in the accurate use of words is afforded by experimental chemistry. Everyone who is about to enter on an inquiry, whether he be a first-year's student who wants to find the constituents of a common salt, or whether he be the most skilled and experienced of chemists, seeks beforehand to get such information from the records of previous observations as may be most useful for his purpose. This information he obtains through the medium of words; and any failure on his part to understand the precise meaning of the words conveying the information requisite for his guidance is liable to lead him astray. Those elementary exercises in analytical chemistry, in which brief directions to the students alternate with their experiments and their reports of experiments made and conclusions drawn, afford a singularly effective training in the habit of attending accurately to the meaning of words used by others, and of selecting words capable of conveying without ambiguity the precise meaning intended. Any inaccuracy in the student's apprehension of the directions given, or in the selection of words to describe his observations and conclusions, is at once detected, when the result to which he ought to have arrived is known beforehand to the teacher.

Accuracy of reasoning is no less effectively promoted by the work of experimental chemistry. It is no small facility to us that the meaning of the words which we use to denote properties of matter and operations can be learnt by actual observation. Moreover, each proposition comprised in chemical reasonings conveys some distinct statement susceptible of verification by similar means; and the validity of each conclusion can be tested, not only by examining whether or not it follows of necessity from true premises, but also by subjecting it to the independent test of special experiment.

Chemists have frequent occasion to employ arguments which indicate a probability of some truth; and the anticipations based upon them serve as guides to experimental inquiry by suggesting crucial tests. But they distinguish most carefully such hypotheses from demonstrated facts.

Thus a pale green solution, stated to contain a pure metallic salt, is found to possess some properties which belong to salts of iron. Nothing else possesses these properties except salts of nickel; and they manifest a

slight difference from iron salts in one of the properties observed.

The analyst could not see any appearance of that peculiarity which distinguishes nickel salts; so he concludes that he has probably got iron in his solution, but almost certainly either iron or nickel. He then makes an experiment which will, he knows, give an entirely different result with iron salts and nickel salts; and he gets very distinctly the result which indicates iron.

Having found in the green liquid properties which the presence of iron could alone impart, he considers it highly probable that iron is present. But he does not stop there; for, although the facts before him seem to admit of no other interpretation, he knows that, from insufficient knowledge or attention, mistakes are sometimes made in very simple matters. The analyst therefore tries as many other experiments as are known to distinguish iron salts from all others; and if any one of these leads distinctly to a result at variance with his provisional conclusion, he goes over the whole inquiry again, in order to find where his mistake was. Such inquiries are practised largely by students of chemistry, in order to fix in their minds, by frequent use, a knowledge of the fundamental properties of the common elements, in order to learn by practice the art of making experiments, and, above all, in order to acquire the habit of judging accurately of evidence in natural phenomena. Such a student is often surprised at being told that it is not enough for him to conduct his experiments to such a point that every conclusion except one is contrary to the evidence before him—that he must then try every confirmatory test which he can of the substance believed to be present, and ascertain that the sample in his hands agrees, as far as he can see, in all properties with the known substance of which he believes it to be a specimen.

Those who tread the path of original inquiry, and add to human knowledge by their experiments, are bound to practise this habit with the most scrupulous fidelity and care, or many and grave would be the mistakes they would make.

Thus a chemist thinks it probable that he might prepare some well-known organic body of the aromatic family by a new process. He sets to work and obtains a substance agreeing in appearance, in empirical composition, in molecular weight, and in many other properties with the compound which he had in view. He is, however, not satisfied that his product is a sample of that compound until he has examined carefully whether it possesses all the properties which are known to belong to the substance in question. And many a time is his caution rewarded by the discovery of some distinct difference of melting-point, or of crystalline form, &c., which proves that he has made a new compound isomeric with the one which he expected to make. It seemed probable, from the agreement of the two substances in many particulars, that they might be found to agree in all, and might be considered to be the same compound; but complete proof of that conclusion consists in showing that the new substance agrees with all that we know of the old one.

In the most various ways chemists seek to extend their knowledge of the uniformity of nature; and their reasonings by analogy from particulars to particulars suggest the working hypotheses which lead to new observations. Before, however, proceeding to test the truth of his hypothesis by experiment, the chemist passes in review, as well as he can, all the general knowledge which has any bearing on it, in order to find agreement or disagreement between his hypothesis and the ideas established by past experience. Sometimes he sees that his hypothesis is at variance with some general law in which he has full confidence, and he throws it aside as disproved by that law. On other occasions he finds that it follows of necessity from some known law; and he then proceeds to verify it by experiment, with a confident anticipation of the result. In many cases the hypothesis does not present sufficiently distinct agreement or disagreement with the ideas esta-

blished by previous investigations to justify either the rejection of it or a confident belief in its truth; for it often happens that the results of experience of similar phenomena are not embodied in a sufficiently definite or trustworthy statement to have any other effect than that of giving probability or the contrary to the hypothesis.

Another habit of mind which is indispensable for success in experimental chemistry, and which is taught by the practice of its various operations, is that of truthfulness.

The very object of all our endeavours is to get true ideas of the natural processes of chemical action; for in proportion as our ideas are true do they give us the power of directing these processes. In fact our ideas are useful only so far as they are true; and he must indeed be blind to interest and to duty who could wish to swerve from the path of truth. But if any one were weak enough to make the attempt he would find his way barred by innumerable obstacles.

Every addition to our science is a matter of immediate interest and importance to those who are working in the same direction. They verify in various ways the statements of the first discoverer, and seldom fail to notice further particulars, and to correct any little errors of detail into which he may have fallen. They soon make it a stepping-stone to further discoveries. Anything like wilful misrepresentation is inevitably detected and made known.

It must not, however, be supposed that the investigator drifts unconsciously into the habit of truthfulness for want of temptation to be untruthful, or even that error presents itself to his mind in a grotesque and repulsive garb, so as to enlist from the first his feelings against it; for I can assure you that the precise contrary of these things happens. Error comes before him usually in the very garb of truth, and his utmost skill and attention are needed to decide whether or not it is entitled to retain that garb.

You will easily see how this happens if you reflect that each working hypothesis employed by an investigator is an unproven proposition, which bears such resemblance to truth as to give rise to hopes that it may really be true. The investigator trusts it provisionally to the extent of trying one or more experiments, of which it claims to predict the specific result. Even though it guide him correctly for a while, he considers it still on trial until it has been tested by every process which ingenuity can suggest for the purpose of detecting a fault.

Most errors which an experimentalist has to do with are really imperfect truths, which have done good service in their time by guiding the course of discovery. The great object of scientific work is to replace these imperfect truths by more exact and comprehensive statements of the order of nature.

Whoever has once got knowledge from Nature herself, by truthful reasoning and experiment, must be dull indeed if he does not feel that he has acquired a new and noble power, and if he does not long to exercise it further, and make new conquests from the realm of darkness by the aid of known truths.

The habit of systematically searching for truth by the aid of known truths, and of testing the validity of each step by constant reference to nature, has now been practised for a sufficiently long time to enable us to judge of some of its results.

Every true idea of the order of nature is an instrument of thought. It can only be obtained by truthful investigation, and it can only be used effectively in obedience to the same laws. But the first idea which is formed of anything occurring in nature affords only a partial representation of the actual reality, by recording what is seen of it from a particular point of view. By examining a thing from different points of view we get different ideas of it; and when we compare these ideas accurately with one another, recollecting how each one was obtained, we find that they really supplement each other.

We try to form in our minds a distinct image of a thing

capable of producing these various appearances; and when we have succeeded in doing so, we look at it from the different points of view from which the natural object had been examined, and find that the ideas so obtained meet at the central image. It usually happens that an accurate examination of the mutual bearings of these ideas on the central image suggests additions to them, and correction of some particulars in them.

Thus it is that true ideas of a natural phenomenon confirm and strengthen one another, and he who aids directly the development of one of them is sure to promote indirectly the consolidation of others.

Each onward step in the search for truth has made us stronger for the work; and when we look back upon what has been done by the efforts of so many workers simply but steadily directed by truth towards further truth, we see that they have achieved, for the benefit of the human race, the conquest of a systematic body of truths which encourages men to similar efforts while affording them the most effectual aid and guidance.

This lesson of the inherent vitality of truth, which is taught us so clearly by the history of our science, is well worthy of the consideration of those who, seeing that iniquity and falsehood so frequently triumph for a while in the struggle for existence, are inclined to take a desponding view of human affairs, and almost to despair of the ultimate predominance of truth and goodness. I believe it would be impossible, at the present time, to form an adequate idea of the vast consequences which will follow from the national adoption of systematic measures for allowing our knowledge of truth to develop itself freely, through the labours of those who are willing and able to devote themselves to its service, so as to strengthen more and more the belief and trust of mankind in its guidance, in small matters as well as in the highest and most important considerations.

I am desirous of describing briefly the more important of those measures; but first let me mention another habit of mind which naturally follows from the effective pursuit of truth,—a habit which might be described in general terms as the application to other matters of the truthfulness imparted by science.

The words which the great German poet put into the mouth of Mephistopheles, when describing himself to Faust, afford perhaps the most concise and forcible statement of what we may call the anti-scientific spirit:—

“Ich bin der Geist der stets verneint,
Dem alles, was entsteht, zuwider ist.”

The true spirit of science is certainly affirmative, not negative, for, as I mentioned just now, its history teaches us that the development of our knowledge usually takes place through two or more simultaneous ideas of the same phenomenon, quite different from one another, both of which ultimately prove to be parts of some more general truth: so that a confident belief in one of those ideas does not involve or justify a denial of the others.

I could give you many remarkable illustrations of this law from among ideas familiar to chemists. But I want you to consider with me its bearing on the habit of mind called toleration, of which the development in modern times is perhaps one of the most hopeful indications of moral improvement in man.

In working at our science we simply try to find out what is true; for although no usefulness is to be found at first in most of our results, we know well that every extension of our knowledge of truth is sure to prove useful in manifold ways. So regular an attendant is usefulness upon truth in our work, that we get accustomed to expect them always to go together, and to believe that there must be some amount of truth wherever there is manifest usefulness.

The history of human ideas, so far as it is written in the records of the progress of science, abounds with instances of men contributing powerfully to the development of important general ideas, by their accurate and conscientious experiments, while at the same time pro-

fessing an actual disbelief in those ideas. Those records must indeed have been a dead letter to any who could stand carping at the intellectual crotchets of a good and honest worker, instead of giving him all brotherly help in the furtherance of his work.

To one who knows the particulars of our science thoroughly, and who knows also what a variety of ideas have been resorted to in working out the whole body of truths of which the science is composed, there are few more impressive and elevating subjects of contemplation than the unity in the clear and bold outline of that noble structure.

I hope that you will not suppose, from my references to Chemistry as promoting the development of these habits and powers of mind, that I wish to claim for that particular branch of science any exclusive merit of the kind, for I can assure you that nothing can be further from my intention.

I conceived that you would wish me to speak of that department of science which I have had occasion to study more particularly; but much that I have said of it might be said with equal truth of other studies, while some of its merits may be claimed in a higher degree by other branches of science. On the other hand, those highest lessons which I have illustrated by chemistry are best learnt by those whose intellectual horizon includes other provinces of knowledge.

Chemistry presents peculiar advantages for educational purposes in the combination of breadth and accuracy in the training which it affords; and I am inclined to think that in this respect it is at present unequalled. There is reason to believe that it will play an important part in general education, and render valuable services to it in conjunction with other scientific and with literary studies.

(To be continued.)

Section B.

ADDRESS

TO THE

CHEMICAL SECTION.

SEPTEMBER 18, 1873.

By W. J. RUSSELL, Ph.D., F.R.S.,
President of the Section.

LADIES AND GENTLEMEN,—

Of late years it has been the custom of my predecessors in this chair to open the business of the Section with an address, and the subject of this address has almost invariably been a review of the progress of Chemistry during the past year: I purpose, with your leave, to-day to deviate somewhat from this precedent, and to limit my remarks, as far as the progress of Chemistry is concerned, to the history of one chemical substance. The interest and the use of an annual survey at these meetings of the progress of Chemistry has to a certain extent passed away; for the admirable abstracts of all important chemical papers now published by the Chemical Society has, in a great measure, taken its place, and offers to the chemical student a much more thorough means of learning what progress his science is making than could possibly be done by the study of a presidential address. Doubtless these abstracts of chemical papers are known to others than professional chemists; but I cannot pass them over without recording the great use they have proved to be, how much they have done already in extending in this country an exact knowledge of the progress of science on the Continent, and in helping and in stimulating those who are engaged in scientific pursuits in this country. I believe few grants made by this Association have done more real good than those which have enabled the Chemical Society to publish these abstracts.

I dwell for a moment on the doings of the Chemical Society, for I believe in the progress of this Society we

have a most important indication of the progress of chemical science in this country. The number of original papers communicated to the Society during the last year has far exceeded that of previous years; during last year fifty-eight papers were read to the Society, whereas the average number for the last three years is only twenty-nine. Further, I may say there is every appearance of this increased activity not only continuing but even increasing. Another matter connected with the Society deserves a passing word: I mean its removal from its old rooms at Burlington House, which afforded it very insufficient accommodation, to its new ones in the same building. This transference, which is now taking place, will give to the Society a great increase of accommodation, and thus admit of larger audiences attending the lectures, of the proper development of the library, and of the full illustration, by experiment, of the communications made to it. These improvements must act most beneficially on the Society, and stimulate its future development: even now it numbers some 700 members, and certainly is not one of the least active or least useful of the many scientific societies in London.

Since our last Meeting at Brighton we have lost the most renowned of modern chemists, Liebig. His influence on chemistry through a long and most active life has yet to be written. Publishing his first paper fifty years ago, it is difficult for chemists of the present day to realise the changes in chemical thought, in chemical knowledge, and in chemical experiment which he lived through, and was, more than any other chemist, active in promoting. His activity was unwearied; he communicated no less than 317 papers to different scientific journals, and almost every branch of chemistry received some impetus from his hand.

Liebig took an active interest in this Association, and I believe the last paper he wrote was one in answer to a communication made at the last Meeting of this Association. On two occasions he attended Meetings of the British Association, and has communicated many papers to this Section. The Meeting at Liverpool in 1837 was the first at which he was present; he then communicated to this Section a paper on the products of the decomposition of Uric Acid, and, further, gave an account of his most important discovery, made in conjunction with Wöhler, of the artificial formation of Urea. At this Meeting Liebig was requested to prepare a report on the state of our knowledge of isomeric bodies. This request, although often repeated, was never complied with. He was also requested to report on the state of Organic Chemistry and Organic Analysis: thus our Section was evidently desirous of giving him full occupation. At the Meeting in 1840, at Glasgow, a paper on Poisons, Contagions, and Miasms, by Liebig, was read; it was, in fact, an abstract of the last chapter in his book on Chemistry in its applications to Agriculture and Physiology; and the work itself appeared about the same time, dedicated to this Association. In his dedication Liebig says:—"At one of the meetings of the Chemical Section of the British Association for the Advancement of Science, the honourable task of preparing a Report upon the State of Organic Chemistry was imposed upon me. In this present work I present the Association with a part of this Report."

At the next Meeting, which was at Plymouth, in 1841, there was an interesting letter from Liebig to Dr. Playfair, read to our Section; in it, among other matters, Liebig describes an "excellent method," devised by Drs. Will and Varrentrapp, for determining the amount of nitrogen in organic bodies: he also says we have repeated all the experiments of Dr. Brown on the production of silicon from paracyanogen, but we have not been able to confirm one of his results; what our experiments prove is, that paracyanogen is decomposed by a strong heat into nitrogen gas and a residue of carbon, which is exceedingly difficult of combustion.

To the next Meeting (which was at Manchester, and

Dalton was the President of this Section) Dr. Playfair communicated an abstract of Prof. Liebig's report on Organic Chemistry applied to Physiology and Pathology: this abstract is printed in our *Proceedings*, and the complete work is looked upon as the second part of the report on Organic Chemistry. This Association may therefore fairly consider that it exercised some influence on Liebig in the production of the most important works that he wrote. Playfair's abstract must have been listened to with the greatest interest, and I doubt not the statements made were sharply criticised, especially by the physiologists then at Manchester. Playfair concludes his abstract in these words, thus summing up the special objects of these reports:—"In the opinion of all, Liebig may be considered a benefactor to his species for the interesting discoveries in agriculture published by him in the first part of this report. And having in that pointed out means by which the food of the human race may be increased, in the work now before us he follows up the chain in its continuation, and shows how that food may best be adapted to the nutrition of man. Surely there are no two subjects more fitted than these for the contemplation of the philosopher; and by the consummate sagacity with which Liebig has applied to their elucidation the powers of his mind, we are compelled to admit that there is no living philosopher to whom the Chemical Section could have more appropriately entrusted their investigation."

At the Meeting at Glasgow in 1855 Liebig was also present, but he then only communicated to this Section a short paper on fulminic acid, and some remarks on the use of lime-water in the manufacture of bread.

Such, I believe, is the history of the direct relationship which has existed between Liebig and this Association. Indirectly we can hardly recognise how much we owe to him. Interested as he ever was in the work of this Association, I could not but to-day record the instances of direct aid and support which this Section has received from him.

I pass on now to the special subject to which I wish to ask your attention. It is the history of the vegetable colouring matter found in madder: it has been in use from time immemorial, and is still one of the commonest and most important of dyes: it is obtained from a plant largely cultivated in many parts of the world for the sake of the colour it yields; and the special interest which now attaches to it is that the chemist has lately shown how this natural colouring matter can be made in the laboratory as well as in the fields—how by using a by-product which formerly was without value, thousands of acres can be liberated for the cultivation of other crops, and the colouring matter which they formerly produced be cheaper and better prepared in the laboratory or in the manufactory. That a certain colouring matter could be obtained from the roots of the *Rubia tinctorum* and other species of the same plant has been so long known that apparently no record of its discovery remains. Pliny and Dioscorides evidently allude to it. The former, referring to its value as a dyeing material, says—"It is a plant little known, except to the sordid and avaricious; and this because of the large profits obtained from it, owing to its employment in dyeing wool and leather." He further says—"The madder of Italy is the most esteemed, and especially that grown in the neighbourhood of Rome, where and in other places it is produced in great abundance." He further describes it as being grown among the olive-trees, or in fields devoted especially to its growth. The madder of Ravenna, according to Dioscorides, was the most esteemed. Its cultivation in Italy has been continued till the present time, and in 1863 the Neapolitan provinces alone exported it to the value of more than a quarter of a million sterling. At the present day we are all very familiar with this colouring matter as the commonest that is applied to calicoes: it is capable of yielding many colours, such as red, pink, purple, chocolate, and black. The plant which is the source of this colouring matter is nearly allied, botanically and in ap-

pearance, to the ordinary *Galiums* or bedstraws. It is a native probably of Southern Europe, as well as Asia. It is a perennial, with herbaceous stem, which dies down every year; its square-jointed stalk creeps along the ground to a considerable distance, and the stem and leaves are rough, with sharp prickles. The root, which is cylindrical, fleshy, and of a pale yellow colour, extends downwards to a considerable depth: it is from this root (which, when dried, is known as madder) that the colouring matter is obtained. The plant is propagated from suckers or shoots; these require some two or three years to come to full maturity and yield the finest colours, although in France the crop is often gathered after only eighteen months' growth. From its taking so long to develop, it is evidently a crop not adapted to any ordinary series of rotation of crops. The plant thrives best in a warm climate, but has been grown in this country and in the north of Europe.

In India it has been grown from the earliest times, and, as before stated, has been abundantly cultivated in Italy certainly since the time of Pliny; he also mentions its cultivation in Galilee. In this country its culture has often been attempted, and has been carried on for a short time, but never with permanent success. The madder now used in England is imported from France, Italy, Holland, South Germany, Turkey, and India. In 1857 the total amount imported into this country was 434,056 cwts., having an estimated value of £1,284,989; and the average annual amount imported during the last seventeen years is 310,042 cwts., while the amount imported last year (1872) was 283,274 cwts., valued at £922,244. In 1861 it was estimated that in the South Lancashire district alone 150 tons of madder were used weekly, exclusive of that required for preparing garancin. I quote these figures as showing the magnitude of the industry that we are dealing with. Another point of much interest is the amount of land required for the cultivation of this plant: in England it was found that an acre yielded only from 10 to 20 cwts. of the dried roots, but in South Germany and in France the same amount of land yields about twice that quantity. The madder cultivator digs up the roots in autumn, dries them, in some cases peels them by beating them with a flail, and exports them in the form of powder, whole root, or after treatment with sulphuric acid, when it is known as garancin.

The quality of the root varies much; that from the Levant, and known as Turkey-root, is most valued. According, however, to the colour to be produced is the madder from one source or another preferred. To obtain the colouring matter, which is but very slightly soluble in water, from these roots, they are mixed, after being ground, with water in the dye-vessel, and sometimes a little chalk is added. The fabric to be dyed is introduced, and the whole slowly heated; the colouring matter gradually passes from the root to the water, and from the water to the mordanted fabric, giving to it a colour dependent of course on the nature of the mordant.

To trace the chemical history of this colouring matter we have to go back to the year 1790, when a chemist of the name of Watt precipitated the colouring matter of madder by alum from neutral, alkaline, and acid solutions; he obtained two different colouring matters, but could not isolate them, and many different shades of colour. Charles Batholdi asserted that madder contained much magnesian sulphate, and Hausmann observed the good effect produced on madder by the addition of calcic carbonate. In 1823 F. Kuhlmann made evidently a careful analysis of the madder root, and describes a red and a fawn colouring matter; but the first really important advance made in our knowledge of the chemical constitution of this colouring matter was by Colin and Robiquet in 1827; they obtained what they believed to be, and what has since really proved to be, the true colouring principle of madder, and obtained it in a state of tolerable purity. Their process for preparing it was very simple: they took Alsace madder in powder, digested it with water, obtained thus a gelatinous mass,

which they treated with boiling alcohol, then evaporated off four-fifths of the alcohol, and treated the residue with a little sulphuric acid to diminish its solubility; then, after washing it with several litres of water, they got a yellowish substance remaining. Lastly, they found that, on moderately heating this product in a glass tube, they obtained a yellowish vapour formed of brilliant particles, which condensed, giving a distinct zone of brilliant needles, reflecting a colour similar to that from the native lead chromate. They named this substance alizarin, from the Levant name for madder, *alisari*, the name by which it is still known there.

A few years later we find other chemists attacking this same subject. In 1831, Gaultier de Claubry and J. Persoz published the account of a long research on the subject; they describe two colouring matters, a red and a rose one: the red one was alizarin, and the rose one was another body nearly allied to it, and now well-known as purpurin. Runge also made an elaborate examination of the madder-root; he found no less than five different colouring matters in it—madder-red, madder-purple, madder-orange, madder-yellow, and madder-brown. The first three he considers to be suited for dyeing purposes, but not so the last two. Runge's madder-red is essentially impure alizarin, and his madder-purple impure purpurin. He does not give any analysis of these substances.

During the next ten years this subject seems to have attracted but little attention from chemists; but in 1846 Shiel prepared the madder-red and madder-purple of Runge by processes very similar to those employed by Runge, and analysed these substances: for madder-red he gives the formula $C_{28}H_{18}O_9$, which differs only by H_2O from the formula now adopted; for the madder-purple he gives the formula $C_{28}H_{20}O_{15}$, and for the same substance after being sublimed $C_{28}H_{18}O_4$. The chemist who has worked most on this subject, and to whom we are principally indebted for what we know with regard to the different constituents contained in the madder-root, is Dr. Schunck, of Manchester. In Liebig's "Annalen" for 1848 he gives a long and interesting account of his examination of madder; he isolates and identifies several new substances, which are most important constituents of the root, and has since that time added much to our knowledge of the chemical constitution of madder. In the paper above alluded to he confirms the presence of the alizarin, and gives to it the formula $C_{14}H_{10}O_4$. The principal properties of this body may best be sketched in here. Its volatility and brilliant crystalline appearance have already been mentioned; it is but slightly soluble in cold water, but much more so in alcohol, in ether, and in boiling water. The colour of its solution is yellow; and when it separates out from a liquid it has a yellow flocculent appearance, differing thus greatly from the red brilliant crystalline substance before described. In order to obtain this latter body, heat had always been used; so, until the elaborate experiments of Schunck, it was a question whether the heat did not produce a radical change in the substance, whether, in a word, these two bodies were really identical. Schunck's experiments proved that they were, and consequently that this beautiful colouring matter, alizarin, existed as such in madder. If, however, we go one step further back, and examine the fresh root of the *Rubia tinctorum* (that is, as soon as it is drawn from the ground), we shall find no trace of alizarin there. On slicing the root it is seen to be of a light carotty colour, and an almost colourless liquid can be squeezed out of it; but this is entirely free from the colouring matters of madder. Let the roots, however, be kept, if only for a short time, and then they will give abundant evidence of the presence of alizarin; if simply heated, alizarin may be volatilised from them. It appears, then, that the whole of the tinctorial power of this root is developed after the death of the plant. Schunck explains this curious phenomenon as follows:—In the cells of the living plant there is a substance which he has isolated and has named rubian; it is easily soluble in water and in alcohol; the

solution is of a yellow colour, and has an intensely bitter taste; when dry, it is a hard brown gum-like body. It has none of the properties of a dye-stuff; but if we take a solution of it, add some sulphuric or hydrochloric acid to it, and boil, a yellow flocculent substance will slowly separate out, and, on filtering it off and washing it, it will be found to have the tinctorial properties of madder, and to contain alizarin. In the liquid filtered from it there is, with the acid added, an uncrystallisable sugar; so that in this way the original product in the root, the rubian, has apparently been split up into alizarin and into sugar. To apply this reaction to what goes on in the root after its removal from the ground, we have to find if any other substances can take the place of the boiling dilute acid; and Schunck has shown there exists in the root itself a substance which is eminently fitted to produce this splitting-up of the rubian. He obtained this decomposing agent from madder simply by digesting it in cold water and adding alcohol to the liquid; this threw down a reddish flocculent substance; and, if only a small portion of this was added to an aqueous solution of the rubian, and allowed to stand for a few hours in a warm place, it was found that the rubian was gone, and in place of it there was a thick tenacious jelly; this, treated with cold water, gave to it no colour, no bitter taste, but much sugar. From the jelly remaining insoluble, alizarin could be extracted; in fact, of all known substances this very one found in the madder itself is best suited for effecting this decomposition of the rubian.

It has long been known to dyers that the amount of colouring matter in madder will increase on keeping it; even for years it will go on improving in quality; and an experiment of Schunck's shows that the ordinary madder, as used by the dyer, has not all the rubian converted into colouring matter; for, on taking a sample of it and extracting it with cold water, he got an acid solution devoid of dyeing properties; but, on allowing this solution to stand some time, it gelatinised, and then possessed dyeing properties.

It appears, then, that there must exist in the root two substances kept apart during the life of the plant in some way of which we know nothing; but as soon as it dies they begin slowly to act on one another, developing thus the colouring matters in madder.

Coincident with the appearance of Schunck's first paper was one by Debus on the same subject: he looked upon alizarin as a true acid, and gave it the name of lizaric acid; but, as far as the composition of it was concerned, the percentage numbers he obtained agreed closely with those given by Schunck. One other investigation concludes all that is important in the history of alizarin as obtained from madder. This last investigation is of great interest; it was by Julius Wolff and Adolphe Strecker, and published in 1850; they confirm the results of others so far that there are in the madder-root two distinct colouring substances—this important one alizarin, and the other one purpurin. They prepare these colouring matters much in the same way that Schunck did, and very carefully purify and analyse them: the formulae which they give for them differ, however, from Schunck's; for alizarin they give the formula $C_{20}H_{12}O_6$, and for purpurin $C_{18}H_{12}O_6$. Further, they suggest that, by the process of fermentation, the former is converted into the latter, and they show that by oxidation they both yielded phthalic acid. Since the publication of this research, until the last year or two, this formula for alizarin has been generally adopted by chemists, and in most modern books we find it given as expressing the true composition of that body. It was not only the careful and elaborate work which they devoted to the subject, but also the ingenious and apparently well-founded theory on the subject, which carried conviction with it. Laurent had shown, not many years before, that when naphthalin, that beautiful and white crystalline substance obtained from coal-tar, was acted on by chlorine, and then treated with nitric acid, a body, known as chlornaphthalic acid, and having the composition

$C_{20}H_{10}Cl_2O_6$, was obtained; and, on comparing this formula with the one they had obtained for alizarin, Wolff and Strecker at once concluded that it really was alizarin, only containing 2 atoms of chlorine in place of 2 of hydrogen; make this replacement, an operation generally easily performed, and from naphthalin they had prepared alizarin. Further, this relationship between chlor-naphthalic acid and alizarin is borne out in many ways; it, like alizarin, has the power of combining with different basic substances, has a yellow colour, is insoluble in water, melts at about the same temperature, is volatile, and when acted on by alkalis gives a strongly coloured solution. Taking, then, all these facts into consideration, can we wonder that these chemists feel convinced that they have established the composition of alizarin, and have shown the source from which it is to be obtained artificially? Apparently but one very simple step remains to crown their work with success, that of replacing the chlorine by hydrogen. Melsens had only shortly before shown how this substitution could easily be made in the case of chloracetic acid, by acting on it with potassium amalgam; and Kolbe had used the battery for the same purpose: both these processes, and doubtless all others that the authors can think of, are tried upon the chlor-naphthalic acid; but chlornaphthalic acid it remains, and they are obliged to confess they are unable to make this substitution; still they are strong in the belief that it is to be done and will be done, and conclude the account of their researches by pointing out the great technical advantage it will be getting alizarin from a worthless substance such as naphthalin. One cannot help even now sympathising with these chemists in their not being able to confirm what they had really the strongest evidence for believing must prove to be a great discovery. We now know, however, that had they succeeded in effecting this substitution, or had they in any other way obtained this chlornaphthalic acid without the chlorine, if I may so speak of it, which since their time has been done by Martius and Griess, alizarin would not have been obtained, but a body having a remarkable parallelism in properties to it would have been. This body, like alizarin, is of a yellowish colour, but slightly soluble in water, easily in alcohol and in ether, is volatile, and on oxidation yields the same products; it is, in fact, an analogous body, but belonging to another group. We also now know that the formula proposed by Wolff and Strecker, and so long in use, is not the correct one. But little more remains to be added with regard to the history of alizarin, as gathered from the study of the natural substance. Schützenberger and Paraf suggested doubling Wolff and Strecker's formula for alizarin; and Bolley suggested the formula $C_{20}H_{13}O_6$, which, owing to the uneven number of hydrogen atoms, was soon rejected. If we compare our present knowledge of alizarin with what it was when these researches on the natural product were completed, it is as lightness compared to darkness; and we may well ask, whence has come this influx of knowledge? The answer, I hope to show you, is undoubtedly that it has come from the careful and accurate study of abstract chemistry. I know of no history in the whole of chemistry which more strikingly illustrates how the prosecution of abstract science lays the foundation for great practical improvements than the history of alizarin does.

My object now is, then, to show you, as shortly as I can, how by indirect means the composition of alizarin was discovered, how it has been built up artificially, and how it is superseding for manufacturing purposes the long-used natural product.

To trace this history from its source we must go back to 1785, when an apothecary of the name of Hofmann obtained the calcium salt of an acid called quinic acid from Cinchona bark. This acid is now known to be of common occurrence in plants; it exists in the bilberry and in coffee, in holly, ivy, oak, elm, and ash leaves, and probably many other leaves. Liebig also prepared the calcium salt, and was the first to give a complete analysis

of it; the formula he gave for it was $C_{15}H_{24}O_{12}$. Baup, on repeating Liebig's experiments, arrived at a somewhat different conclusion, and gave the formula $C_{15}H_{20}O_{10}$. In 1835, at Liebig's suggestion to determine which formula was correct, Alexander Woskrensky, from St. Petersburg, then a student at Giessen, undertook the further investigation of this subject, and established the formula $C_{14}H_{24}O_{12}$, the one in fact now in use. In the course of this investigation, which he carried further than merely settling the percentage composition of this acid, he describes what to us now is of most interest, a new substance having peculiar and very marked properties. He says that when a salt of quinic acid is burnt at a gentle heat he gets aqueous vapour, the vapour of formic acid, and a deposit of golden needles, which are easily sublimed; afterwards he describes how this same golden substance may be obtained from any salt of quinic acid by heating it with manganic dioxide and dilute sulphuric acid; it then distils over, condensing in golden-yellow needles on the sides of the receiver, and may be rendered pure by re-sublimation. The composition of this body he finds to be C_3H_2O , and names it quinoyl, a name strongly objected to by Berzelius, as conveying a wrong impression of the nature of the body; he proposed in place of it the name quinone, by which it is still known. Far as this body would seem to be removed from alizarin, yet it is the study of its properties which led to the artificial production of alizarin.

Some years afterwards Wöhler also examined the decomposition of quinic acid; he prepares again this quinone, and follows exactly the process described by Woskrensky: he states that, with regard to the properties of this remarkable body, he has nothing particular to add; however, he proposes a different formula for it, and discovers and describes other bodies allied to it; among these is hydroquinone, $C_6H_6O_2$. Laurent afterwards shows that the formula proposed by Wöhler is inconsistent with his and Gerhardt's views, and by experiment confirms the former formula for this body. Although many other chemists devoted much attention to this substance, still its real constitution and relation to other compounds remained long unknown. Thus Wöhler, Laurent, Hofmann, Städeler, and Hesse all had worked at it, and much experimental knowledge with regard to it had been acquired. One important point in its history was, first, the discovery of chloranil by Erdmann in 1841, and then Hofmann showing that by heating quinone with potassic chlorate and hydrochloric acid, chloranil could be obtained from it—that, in fact, chloranil was quinone in which all the hydrogen had been replaced by chlorine. Perhaps the most general impression among chemists was, that in constitution it was a kind of aldehyd; certainly its definite place among chemical compounds was not known. Kekulé suggests a rational formula for it; but it is to Carl Græbe that we owe our knowledge of its true constitution. In 1868 he published a remarkable and very able paper on the quinone group of compounds, and then first brought forward the view that quinone was a substitution derivative of the hydrocarbon benzol (C_6H_6). On comparing the composition of these two bodies, it is seen that the quinone contains 2 atoms of oxygen more, and 2 atoms of hydrogen less, than benzol; and Græbe, from the study of the decomposition of quinone and from the compounds it forms, suggested that the 2 atoms of oxygen form in themselves a group which is divalent, and thus replace the two atoms of hydrogen; this supposition he very forcibly advocates, and shows its simple and satisfactory application to all the then known reactions of this body. This suggestion really proved to be the key, not only to the explanation of the natural constitution of quinone and its derivatives, but to much important discovery besides.

At this time quinone seemed to stand alone, no other similarly constituted body was known to exist; but what strikingly confirms the correctness of Græbe's views, and indicates their great value, is that immediately he is able

to apply his lately gained knowledge, and to show how really other analogous bodies, other quinones in fact, already exist. He studied with great care this quinone series of compounds and the relation they bore to one another—the relation the hydrocarbon benzol bore to its oxidised derivative quinone, and its relation to the chlorine substitution-products derivable from it. At once this seems to have led Græbe to the conclusion that another such series already existed ready formed, and that its members were well known to chemists—that, in fact, naphthalin ($C_{10}H_8$) was the parent hydrocarbon, and that the chloroxynaphthalin chloride ($C_{10}H_4Cl_2O_2$) and the perchloroxynaphthalin chloride ($C_{10}Cl_6O_2$) were really chlorine substitution-compounds of the quinone of this series, corresponding to the bichloroquinone and to chloranil—that the chloroxynaphthalic acid, $C_{10}H_4Cl(HO)O_2$, and the perchloroxynaphthalic acid, $C_{10}Cl_5(HO)O_2$, all compounds previously discovered by Laurent, were really bodies belonging to this series—and, further, that the supposed isomer of alizarin discovered by Martius and Griess was really related to this last compound, having the composition $C_{10}H_5(HO)O_2$. Further, he was able to confirm this by obtaining the quinone itself of this series, the body having the formula $C_{10}H_6(O_2)''$, containing also 2 atoms less of hydrogen and 2 atoms more of oxygen than the hydrocarbon naphthalin; and to this body he gave the characteristic name of naphthoquinone. The chlorine compounds just named are, then, chlornaphthoquinones or chloroxynaphthoquinones, and correspond to the former chloroquinones; and Martius and Griess's compound will be an oxynaphthoquinone: many other compounds of this series are also known. Another step confirmatory of this existence of a series of quinones was made by Græbe and Bergmann: as the chloranil could be found by treating phenol with potassic chlorate and hydrochloric acid, and quinone derived from it, they showed that in the next higher series to the phenol series, viz., with cresol, the same reaction held good; and by treating it in the same way, they obtained a di- and a trichloro-toluquinone—

which in physical properties very closely resembled the corresponding compounds in the lower series: other compounds have also been prepared.

In the next step we have the application which connects these series of discoveries with alizarin. Following the clue of a certain analogy which they believed to exist between the chloranilic acid—

and the chloroxynaphthalic acid—

which they had proved to be quinone compounds and alizarin, believing that a certain similarity of properties indicated a certain similarity of constitution, Græbe and Liebermann were led to suppose that alizarin must also be a derivative from a quinone, and have the formula—

This theory they were able afterwards to prove. The first thing was to find the hydrocarbon from which the quinone might be derived. This was done by taking alizarin itself and heating it with a very large excess of zinc powder in a long tube closed at one end. A product distilled over, and condensed in the cool part of the tube. On collecting it and purifying it by re-crystallisation, they found they had not a new substance, but a hydrocarbon discovered as long ago as 1832 by Dumas and Laurent, and obtained by them from tar. They had given it the formula $C_{14}H_{12}$; and as apparently it thus contained once and a half as many atoms of carbon and hydrogen as

naphthalin did, they named it paranaphthalin. Afterwards Laurent changed its name to anthracen, by which it is still known. Fritzsche, in 1857, probably obtained the same body, but gave it the formula $C_{14}H_{10}$. Anderson also met with it in his researches, established its composition, and formed some derivatives from it. Limpricht in 1866 showed it could be formed synthetically by heating benzol chloride (C_7H_7Cl) with water; and Berthelot has since proved that it is formed by the action of heat on many hydrocarbons. This first step was then complete and most satisfactory; from alizarin they had obtained its hydrocarbon, and this hydrocarbon was a body already known, and with such marked properties that it was easy to identify it. But would the next requirement be fulfilled? would it, like benzol and naphthalin, yield a quinone? The experiment had not to be tried; for when they found that anthracen was the hydrocarbon formed, they recognised in a body already known the quinone derivable from it. It had been prepared by Laurent by the action of nitric acid on anthracen, and called by him Anthracenase; and the same substance was also discovered by Anderson, and called by him Oxanthracen. The composition of this body was proved by Anderson and Laurent to be $C_{14}H_6O_2$, and thus bears the same relation to its hydrocarbon anthracen that quinone and naphthoquinone do to their hydrocarbons. Græbe gave to it the systematic name of Anthraquinone.

We have then now three hydrocarbons— C_6H_6 , $C_{10}H_8$, and $C_{14}H_{10}$ —differing by C_4H_2 , and all forming starting-points for these different quinone series. Anthraquinone, acted upon by chlorine, gave substitution-products such as might have been foretold. It is an exceedingly stable compound, not acted upon even by fusion with potassic hydrate. Bromine does not act upon it in the cold, but at 100° it forms a bibromanthraquinone. Other bromine compounds have also been formed.

Now, if the analogies which have guided them so far still hold good, they would seem to have the means of forming alizarin artificially. Their theory is that it is dioxanthraquinone—

and if so, judging from what is known to take place with other quinone derivatives, should be formed from this dibromanthraquinone on boiling it with potash or soda and then acidulating the solution. They try the experiment, and describe how, contrary at first to their expectation, on boiling dibromanthraquinone with potash no change occurred; but afterwards, on using stronger potash and a higher temperature, they had the satisfaction of seeing the liquid little by little become of a violet colour. This shows the formation of alizarin. Afterwards, on acidifying this solution, the alizarin separated out in yellowish flocks. On volatilising it they get it in crystals like those obtained from madder; on oxidising it with nitric acid, they get phthalic acid; and on precipitating it with the ordinary mordants or other metallic solutions, they get compounds exactly comparable to those from the natural product. Every trial confirms their success; so, by following purely theoretical considerations, they have been led to the discovery of the means of artificially forming this important organic colouring matter. A special interest must always attach itself to this discovery, for it is the first instance in which a natural organic colouring matter has been built up by artificial means. Now the chemist can compete with nature in its production. Although the first, it is a safe prediction that it will not long be the only one. Which colouring matter will follow next it is impossible to say; but, sooner or later, that most interesting one, scientifically and practically indigo, will have to yield to the scientific chemist the history of its production.

Returning for a moment to the percentage composition of alizarin, now that we know its constitution, its formula is established; and on comparing it ($C_{14}H_6O_4$) with all the different formulæ which have been proposed, we see

that the one advocated by Schunck was most nearly correct—in fact, that it differs from it only by 2 atoms of hydrogen. It is not without interest to note that the next most important colouring matter in madder, purpurin, which so pertinaciously follows alizarin, is in constitution very nearly allied to it, and is also an anthracen derivative.

Scientifically, then, the artificial production of this natural product was complete; but the practical question, Can it be made in the laboratory cheaper than it can be obtained from the root? had yet to be dealt with. The raw material, the anthracen, a by-product in the manufacture of coal-gas, had as yet only been obtained as a chemical curiosity; it had no market value; its cost would depend on the labour of separating it from the tar and the amount obtainable. But with regard to the bromine necessary to form the bibromanthraquinone it was different; the use of such an expensive reagent would preclude the process becoming a manufacturing one. But could no cheaper reagent be used in place of the bromine, and thus crown this discovery by utilising it as a manufacturing process? It was our countryman Mr. Perkin who first showed how this could be done, and has since proved the very practical and important nature of his discovery by carrying it out on the manufacturing scale. The nature of Perkin's discovery was the forming, in place of a bibromanthraquinone, a disulphoanthraquinone; in a word, he used sulphuric acid in place of bromine, obtaining thus a sulpho-acid in place of a bromine substitution-compound. The properties of these sulpho-acids, containing the monovalent group HSO_3 , which is the equivalent to the atom of bromine, is that on being boiled with an alkali they are decomposed, and a corresponding alkaline salt formed. Thus the change from the anthraquinone to the alizarin was effected by boiling it with sulphuric acid. At a high temperature it dissolves, becoming a sulpho-acid—

and then the further changes follow, as they did with the bromine compound. The sulpho-acid boiled with potash is decomposed, and a potash salt of alizarin and potassic sulphite are formed; acid then precipitates the alizarin as a bright yellow substance.

While Perkin was carrying on these researches in this country, Caro, Græbe, and Liebermann were carrying on somewhat similar ones in Germany; and in both countries have the scientific experiments developed into manufacturing industries. My knowledge extends only to the English manufactory; and if any excuse be necessary for having asked your attention to-day to this long history of a single substance, I think I must plead the existence of that manufactory as my excuse; for it is not often that purely scientific research so rapidly culminates in great practical undertakings. Already has the artificial become a most formidable opponent to the natural product; and in this struggle, already begun, there can be no doubt which will come off victorious.

In the manufactory is rigidly carried out the exact process I have already described to you. In tar there is about 1 per cent of anthracen; this, in a crude impure state, is obtained from it by the tar-distiller and sent by him to the colour works. Here it is purified by pressure, by dissolving from it many of its impurities, and, lastly, by volatilising it. Then comes the conversion of it into the anthraquinone by oxidising agents, nitric or chromic acid being used, then the formation of the sulpho-compound by heating it with sulphuric acid to a temperature of about 260°C . The excess of acid present is then neutralised by the addition of lime, and the insoluble calcic sulphate is filtered off. To the filtered liquid sodic carbonate is added, and thus the calcic salt of the sulpho-acid is changed into the sodic salt—

This is afterwards heated to about 180°C . with caustic soda, thus decomposing the sulpho-acid and forming the soda salt of alizarin and the sodic sulphite. The alizarin salt so formed remains in solution, giving to the liquid a beautiful violet colour. From this solution sulphuric acid precipitates the alizarin as an orange-yellow substance. It is allowed to settle in large tanks, and then is run, in the form of a yellowish mud, which contains either 10 or 15 per cent of dry alizarin, into barrels, and is in this form sent to the print-works, and used much in the same way as the original ground madder was used.

The alizarin mud, as I have called it, containing but 10 per cent of dry alizarin, is equal in dyeing-power to about 8 times its weight of the best madder, and is the pure substance required for the dyeing, in place of a complicated mixture containing certain constituents which have a positively injurious effect on the colours produced.

The scientific knowledge and energy which Mr. Perkin has brought to bear on the manufacture of this colouring matter seem already to have worked wonders. The demand and supply of artificial alizarin are increasing at a most rapid rate, and yet the manufacture of it seems hardly to have commenced. The value of madder has much decreased; and in fact, judging by what occurred in the year of revolution and commercial depression (1848), when the price of madder fell for a time to a point at which it was considered it would no longer remunerate the growers to produce it, that point has now been again reached, but certainly from very different reasons. Last year* artificial alizarin equal in value to about one-fourth of the madder imported into England was manufactured in this country. This year the amount will be much larger.

Thus is growing up a great industry, which, far and wide, must exercise most important effects. Old and cumbrous processes must give way to better, cheaper, newer ones; and, lastly, thousands of acres of land in many different parts of the world will be relieved from the necessity of growing madder, and be ready to receive some new crop. In this sense may the theoretical chemist be said even to have increased the boundaries of the globe.

ON THE ENERGIES OF THE IMPONDERABLES, WITH ESPECIAL REFERENCE TO THE MEASUREMENT AND UTILISATION OF THEM.†

By the Rev. ARTHUR RIGG, M.A.

(Continued from page 141.)

LECTURE IV.

The Energy of Affinity, especially with reference to Considerations for the Measurement and Utilisation of it.

THE energy of affinity assumes many Protean forms, embracing facts in very opposite phases. At one time it seems to hold elemental matter in adamantine chains so firmly that no appliances, such as heat or light or electricity, can undo the bonds; at another time there seems to be a repellent power of affinity (contradictory though the expression may sound) so influencing, that though every facility for voluntary combination be presented, yet none of these inducements accomplish this combination. For example, the oxygen and nitrogen in the atmosphere, which for all general purposes may be said never to enter combination whilst acting as atmosphere. Again, oil and water—neither shaking nor heating can cause mixture, let alone combination. This repellent power is utilised in vitality thus:—The fluid which lubricates the eyeball would continually pass over the edges of the lids, and so run down the cheeks, were there not glands upon the edge of the lids that secrete a very little oil, and so by

* On the 1st of this month (September) the value of madder-roots in France was 24 to 26 francs per 50 kilogrammes. The average price in 1848 was 27, but in June and July of that year it was 22 francs.

† The Cantor Lectures, delivered before the Society of Arts.

virtue of this "repellent affinity" the ordinary fluid is confined to its appointed channel. If this fluid be excessive, the oily boundary is overflowed, and tears trickle down the cheeks.

On reference to the diagram on the wall, it is stated that the energy of affinity is manifested in mechanical action, and it is probably the source of the mechanical power utilised by men for manufacturing purposes. We find affinity operating under all circumstances in which the character of a resulting compound is different from that of the elementary bodies which constitute the compound. Affinity may be said to be kinetic when converted, and potential when in molecular relation. In other words, all the molecules of one body are somehow or other related by affinity to the molecules of another body, either directly or indirectly, when states of change are occurring. Under these circumstances, until the new molecular relations are called forth, there is potential energy: as these are brought about we get kinetic energy.

The term "Affinity," as employed in this course of lectures, needs an explanation. As a term in science it is fairly derived from that sense in which it ought to be used in conversation or ordinary writing. The word, when properly applied, is in reference to those connections which a marriage may have established between the relatives of the wedded pair. Prior to that marriage there were no relationships; after it, relationships enter by affinity. The relatives of the husband are connected to him by consanguinity, so are the relatives of the wife to her, but after the marriage these two sets of relatives are connected each to the other by affinity. This distinction makes clear that affinities are regarded only as between different bodies. No affinity can exist between lead and lead, or between oxygen and oxygen. As in social life, the legal relationships resulting from affinity and consanguinity are very different, so in science life the atoms which constitute the elementary parts of a simple body, and the molecules which constitute the elementary parts of a compound body, are tied together in bonds of different kinds.

Between atom and atom, or molecule and molecule of a like nature, there are no affinities. True, these are held together, but it is by what is sometimes called the force of cohesion. If atom or molecule of one nature is, thus unchanged, held to an atom or molecule of another nature, then the bond is one of adhesion. If, for example, these two plates of smooth glass be slid one over the other and pressed together they cohere. If gum be dropped on one and the other pressed upon it, they then adhere. Water adheres to many substances of very different constitution.

To cohesion we are indebted for the strength of solids. The cohesive force operates, but in marvellously different degrees, in ice, water, and steam. To adhesion we are indebted for those unions effected by cements, &c. With the intensity of these two subsidiary agents in the work of affinity this lecture is not concerned, although they perform no unimportant parts.

Between affinity, if used as a term in physics, and if used as a term in chemistry, there is this distinction:—Students in physics might classify cohesion and adhesion as branches of affinity. Students in chemistry would not admit the term (affinity) unless the composing elements after the influence of affinity have undergone such a change as to obliterate all traces of the originals. Hence the phrase "chemical" affinity, thus, by the prefix "chemical," excluding the physicist's views.

An experimental illustration may make clear the use of the term "affinity" by the respective students in physics and chemistry.

Here are two solutions, the one of gum dissolved in water, the other of camphor dissolved in spirits of wine. These two are respectively mixed, nevertheless there is in neither case any chemical affinity. If we add pure spirits of wine to the mixture of gum and water, we should destroy what the physicist might call the affinity, but

which the chemist does not admit to be such. On the other hand, if we add water to the solution of camphor we destroy the mixture there; a separation takes place, and in one case the gum, and in the other the camphor, is precipitated. The term "affinity," applied to the unions thus separated, would not to a physicist seem improper; the chemist would not permit the use of this word. It is in the chemist's sense that the word is used in the phrase "energy of affinity." He distinguishes thus:—the term "combination" is applied by him to the results of affinity, and to that which has just been described as a phenomenon in physics the chemist applies the term "mixture."

These preliminary distinctions prepare us for an explanation of what we are to understand by those affinities whose energies are to be considered. Used in a chemical sense, affinity is that power which influences bodies dissimilar in composition, form, and character to combine. The consequence of this union is the formation of new compounds, which may or may not be dissimilar in colour, form, and every fashion, to any of the composing bodies, which may or may not be possessed of properties and characters that are not even traceable in the originals. These compound bodies, thus unlike their progenitors, also establish relationships of affinity, and we are soon surrounded with numerous compounds, so diverse that all traces of the originals are to ordinary apprehensions totally obliterated.

There is, however, amongst these bodies a kind of clanship or caste, similar to that amongst the people of India. Thus, simple or elementary bodies combine only with simple or elementary ones; compound bodies only with compound ones.

For example—Oxygen, which is a simple body, enters into the alliance of affinity with the metals, which are also simple bodies.

Here is some pure metal—lead—in a state of very minute subdivision. It is enclosed in an air-tight glass tube. This lump of lead is exactly the same material. The difference is, that in the finely subdivided metal in the glass tube combination with oxygen will take place the moment it is exposed to the air, so that the atoms of lead which are soon to be shaken out are brought into contact with the oxygen—atom with atom.

Thus, on breaking off the end of the glass tube and shaking out the contents, you see the black particles, as they fall, glow with heat, owing to their rapid combination with the oxygen of the atmosphere. Here is a case of affinity, consequent on a state of subdivision—a case of affinity proper. Mr. Wills, who most kindly this evening gives us the benefit of his chemical knowledge and experimental skill, will now show you how strong is the affinity of oxygen for the steel blade of a knife; when heated and placed in a stream of oxygen the ignited particles of steel in the blade rapidly burn away. The same thing happens if a stream of oxygen is directed on any of the simple metals when raised to a red heat. In a hollow on this tile are some iron nails; by directing a stream of ignited hydrogen in oxygen upon them, the affinity is so strong that they not only melt but boil, and the ebullition is so powerful that a brilliant shower of molten metal is scattered around. Similarly, a piece of zinc when exposed to oxygen is rapidly consumed.

But when we deal with acids which are compounds, they do not ally themselves by affinity with the simple metals, but only with the oxides of the metals, which, like themselves, are compound bodies.

The range of the energies of affinities is very great. For example, oxygen and the metals. Oxygen can with difficulty be induced to unite with gold and platinum—hence these metals do not tarnish in the air; with sodium and potassium the affinities are so strong that the union is rapid enough to generate both light and heat. Either to facilitate or prevent such union, and so promote or retard the energy of affinity, has led to the adoption of various compounds, under the name of fluxes.

It may be well to explain that to this energy of affinity we may be said to owe the variety which the earth possesses. Reduce its compounds into their elements, and a sample of each of all of which the world is made might be arranged on this table. There are now only 63 reputed elements: from the affinities amongst these 63, whether taken by twos, or threes, or fours, or more, everything is made. Indeed, $\frac{1}{100}$ ths of the earth is made of 13 elements; the mathematician's calculation is an easy one which could tell the number of articles that might be formed by combining these 13 by twos, then by threes, then by fours, and so on to 13. There would thus, out of these elements, be 8191 different compounds. This number is very naturally increased from the operation of what may be called the law of combination in multiple and sub-multiple proportions. Allowing another 8191 for these multiples and sub-multiples, there would be in the world composed of these 13 elements 16,382 articles. Such a calculation as this is exceedingly simple, and the mathematician would say must be correct. Affinity, however, enters with a "veto." It claims the right to determine the nature of any combination or set of combinations, and in the exercise of this claim the character and constitution of the combining elements are so completely altered as to have lost all obvious trace of their original, and, therefore, when the combination by threes takes place the result does not partake of the character of any one of the components. This change of character is what the mathematician's calculation does not reckon upon; indeed such a calculation is based upon the physicist's interpretation of the word affinity, and it ignores the chemist's views.

The problem which is now before us is to define a mode of measuring the transformations in every shape introduced by affinity amongst these thirteen elements; a problem very simple, as thus stated, but wondrously complicated,—in fact only capable of an approximate or inferential solution, which is, practically, no solution at all.

In a homely way this difficulty may be illustrated within the walls of many a house. Assume the residents to be a father and mother and thirteen children. Who can tell the combinations consequent upon what may be called the mutual affinities existing amongst these thirteen children? Even from day to day the stability of that family cannot be ensured. The combinations of twos and threes, which yesterday gave promise of permanency, is to-day dissolved, and these molecular children form other alliances. This microcosm of a world is under the influence of new feelings, changed tastes; indeed it passes, with more than electrical rapidity, from a summer-like happiness to a wintry gloom—from a peaceful calm to lurid flashes—and forebodings of domestic storms!

Well, amongst the affinities of the thirteen terrestrial elements similar changes and relations are induced. Whilst we may be able to tell with unerring exactitude how any *two* may act, if left to settle themselves under the sole influence of their dual affinities, when three or four, or more, come together, certain perplexity results.

(To be continued).

NOTICES OF BOOKS.

Scientific Handicraft; a Descriptive, Illustrated, and Priced Catalogue of Apparatus, suitable for the Performance of Elementary Experiments in Physics. By J. J. GRIFFIN, F.C.S. Vol. I.: Mechanics, Hydrostatics, Hydrodynamics, and Pneumatics. London: J. J. Griffin and Sons.

Most of our readers are familiar with Griffin's "Chemical Handicraft," a work which is at once a trade catalogue and, to some extent, a treatise on chemical manipulation. The book before us is an extension of the same idea to other departments of experimental science. It must, however, be noted that the mere trade department is

much less prominent than in "Chemical Handicraft," whilst the amount of information on the use of the various pieces of apparatus and the principles they illustrate is much enlarged. We have no doubt that the work will be found very valuable both to teachers and students in enabling them to select without loss of time the precise articles they may require. In looking over the descriptions and figures of specific gravity bottles, pipette, burettes, &c., we cannot help expressing a wish that the "septem" may at an early date disappear both from graduated apparatus in the laboratory and from the pages of scientific manuals. We ask further,—is it beyond the power of scientific men to agree upon some one standard graduation for hydrometers, both for liquids lighter and for those heavier than water? If the Continent has the advantage over England in the simplicity of its weights and measures, it falls behind us in another respect, owing to the number and complexity of its hydrometric scales.

We presume that the volume before us is the first of a series which will doubtless embrace all the other departments of physical science.

Lectures on Practical Pharmacy. By BARNARD I. PROCTOR. London: J. and A. Churchill.

THE increasing demand for scientific instruction, about which we hear so much, is not always of that tangible nature which leads to permanent results. Those who come forward to meet it often find it vanish away. Of this our author gives a somewhat pathetic instance in his "prefatory letter." About a dozen years ago, in consequence of a local movement, he accepted a lectureship on pharmacy at the Newcastle Pharmaceutical School. "The attendance, at first satisfactory, gradually diminished till, during the third year of the school's existence, I had the honour of reading a paper on Sulphur, and performing the experiments in illustration, before an audience of *one*." Who that has ever accepted the honorary chair in any branch of physical science at a Mechanics' Institute, or any similar body, has not to tell of some analogous experience? Such results wound our vanity, indeed; but they do something more. They convince us that a long time must elapse, or a radical change ensue, before we can hope to overtake our competitors on the other side of the North Sea.

From this abortive pharmaceutical school, and from the pharmacy lectureship subsequently appended to the Newcastle Medical College and held by the author, has sprung the present work. Mr. Barnard modestly proclaims himself as still a student rather than a teacher, and apologises for the want of uniformity in thermometrical scales, weights, and measures, equivalent numbers and nomenclatures made use of. Nomenclatures have, indeed, become so numerous and complicated, that a dictionary of chemical synonyms would be of no trifling utility to all who have to make themselves acquainted with chemical literature.

The work before us contains sections on the principal chemical operations practised in pharmacy; on the various classes of officinal preparations; on dispensing and reading prescriptions, illustrated with lithographed fac-similes of medical kakography; on qualitative and quantitative testing, and on the pharmacy of special drugs. Each section concludes with a brief summary or recapitulation, and questions for self-examination. The various processes are carefully and clearly described, with indication of niceties important to success, but which the student might otherwise overlook. We might instance the lectures on precipitation, crystallisation, diffusion, and dialysis, as happy specimens of the golden mean between the diffuseness that encumbers and the brevity that perplexes. The author contrives, in passing, to point out not a few prevalent errors both in standard works and in vague professional opinion, whilst the only flaw which we have detected is the statement,—probably a typographical error,—that the *sulphate* of antimony treated with strong

hydrochloric acid evolves sulphuretted hydrogen. The illustrations are numerous and appropriate, but a more complete index would have been beneficial. Altogether we must pronounce the work a good specimen of a treatise on chemistry as applied to a special art, and as such we can recommend it to pharmaceutical students and to pharmacists in general.

CORRESPONDENCE.

PREPARATION OF NORMAL ACID.

To the Editor of the Chemical News.

SIR,—I find the following a very easy and accurate method of making a standard acid, and as I have not seen it in any of the books on analysis, perhaps it may be of some use:—

Dilute commercial HCl with ten times its volume of water, pass an excess of SH_2 through the mixture and boil for a few minutes, allow to settle, then filter or decant off the precipitate. It is next to be distilled until 9-roths of the acid has passed over, and the distillate diluted to about 1020 sp. gr.

A piece of Iceland spar (about 8 or 10 grms.) is to be accurately weighed and placed in a flask together with 100 c.c. of the acid as prepared above. A chloride of calcium tube, filled with pieces of glass, is to be fitted to the flask, as in figure. A few drops of solution of litmus (which must be just blue) is to be poured through the CaCl_2 tube into the flask. The contents of the flask must be kept boiling gently until the litmus in it turns blue, then the remains of the crystal is to be taken out, washed, dried, and re-weighed. The loss in weight of the crystal indicating the strength of the acid, the latter can now be standardised. Thus, as 5 is to the loss of weight in grammes of the crystal, so is 100 c.c. to the number of c.c. of the acid, which must be taken and made up to 100 c.c. As the litmus in the CaCl_2 tube remains blue, we know that there has been no loss of acid.—I am, &c.,

The Laboratory, Heywood,
September 9, 1873.

GEORGE DUERR.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Under this heading will be found an encyclopaedic list of chemical papers published abroad during the past week, with abstracts of all susceptible of advantageous abridgment. The two half-yearly volumes of the CHEMICAL NEWS, with their copious indices, will, therefore, be equivalent to an English edition of the "Jahresberichte."

NOTE. All degrees of temperature are Centigrade, unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances de l'Académie des Sciences, August 18, 1873. (Continued).

Secondary Currents and their Applications.—Extract from memoir by M. Planté.—In studying the phenomena of his secondary couples (formed with plates of lead) the author found that the chemical change in the electrodes, which forms the source of the secondary current, is rendered more complete by a primary current being passed alternately in opposite directions, and repose allowed between each double action. By the former, the deposits of oxide are reduced, then recomposed, and the electrodes are thus modified in molecular constitution, not

only at the surface, but by degrees interiorly, giving an increasing effect for years. By the latter (repose) the deposits of oxidised or reduced metal acquire a crystalline texture and a strong adherence, which contributes to protect the subjacent deposits tending to form under the action of the primary current. These operations M. Planté designates the *formation* of secondary couples. A secondary couple with less than half a metre of surface properly formed will, when charged with two Bunsen elements, redden a platinum wire half a m.m. diameter during twenty minutes, or a wire $\frac{1}{8}$ m.m. diameter for an hour, without any communication with the primary source, and even forty-eight hours after being charged. After formation has once been effected the secondary couple may be charged by a current acting always in the same direction. M. Planté exhibited an apparatus so arranged that, by touching a metallic point in a box containing a secondary couple, a platinum wire was heated, and might be used to light a candle, a spirit-lamp, or gas. The primary pile consisted of 3 elements of zinc and water, copper and sulphate of copper. The secondary couple once charged may give a hundred consecutive lightings. With an apparatus somewhat larger one may obtain 3000 to 4000. This mode obviates many disadvantages connected with the use of matches; and it is very economical. For there is no expense connected with the secondary couple; the lead and liquid do not need renewal. And to maintain the weak current of the primary pile necessary to charge the secondary couple one has only to add some crystals of sulphate of copper; the consumption of which is very small compared with the large number of lightings obtainable. M. Planté proposes also to employ his secondary couples for electric bells, and describes how this may be done.

Variations of Urea under the Influence of Caffeine, Coffee, and Tea.—M. Rabuteau.—The author cites his experiments made in 1870 in opposition to those recently made by M. Roux, who considers tea and coffee do not prevent denutrition of tissues.

Sitzungsberichte der Kaiserlichen Akademie der Wissenschaften, Vienna, October, 1872.

On Nicotin.—Dr. H. Weidel.—The author chiefly examined combinations of nicotinic acid, which was obtained by oxidation of nicotin with nitric acid, and to which he gives the formula $\text{C}_{10}\text{H}_8\text{N}_2\text{O}$. The compounds studied were those with nitric acid, hydrochloric acid, bromide of hydrogen, sulphuric acid, hydrochlorate of double salt of platinum, two with silver, and lime. The platinum salt and the lime combinations gave beautiful crystals of the oblique prismatic system. Dr. Weidel further compared with nicotinic acid another acid obtained from nicotin by Huber, by oxidation with chromic acid, viz. $(\text{C}_6\text{H}_5\text{NO}_2)_2$.

On Excretin.—F. Hinterberger.—Marcet regarded excretin as a sulphur-containing substance, with formula $\text{C}_{78}\text{H}_{156}\text{SO}_2$. Hinterberger has succeeded in getting it free from sulphur, and gives as its simplest formula $\text{C}_{20}\text{H}_{30}\text{O}$; which shows a close correspondence to cholesterol, $\text{C}_{26}\text{H}_{44}\text{O}$. But cholesterol is less easily dissolved in vinegar than excretin, and the solution shows in the microscope beautiful sericeous six-sided prisms, while the excretin solution forms round masses. Treated with bromine excretin gave a crystallising compound with formula $\text{C}_{20}\text{H}_{34}\text{Br}_2\text{O}$; but the author did not succeed in preparing chloride of excretin.

Behaviour of Non-Conducting Substances under the Influence of Electrical Forces.—M. L. Boltzmann.—The author deduced from Helmholtz's theory of dielectricity that electric forces may exercise considerable attraction on a non-conductor simply through dielectric polarisation; that a non-conducting ball in a homogeneous electric field should be $\frac{D-1}{D+2}$ times as strongly attracted as a similar and insulated conducting ball acted on by the

same force through induction; D being the constant of dielectricity. In a first series of experiments values of D were obtained with a condenser, a battery, and an electrometer for hard gum, sulphur, paraffin, and colophony. In a second series the method of experiment was briefly as follows:—A ball of the insulating substances was hung by a silk thread at the arm of a delicate balance whose motions were indicated by a small mirror. Near this movable ball was a fixed one which could be charged from a machine with either positive or negative electricity. For the non-conducting ball an equal sized conducting one could be substituted. A second balance with conducting ball suspended near the fixed ball served as measure of the quantity of electricity. Comparison was now made between the attractions of the non-conducting and the conducting balls on the first balance to the fixed ball. The numbers given in a table show how much more the conducting ball was attracted than the non-conducting one. According to the theory of dielectrics these numbers should have the value $\frac{D+1}{D-2}$. The values of D deduced

from this are compared with those from the former measurement. In some cases there is pretty close agreement; in others difference. It was observed that the longer the electric action the more considerable was the dielectric polarisation. M. Boltzmann thinks his method should yield valuable results on the hitherto little studied behaviour of insulators in the electric field. The author further views his numbers in connection with Maxwell's hypothesis that light and electricity are different forms of motion in one and the same medium. Between the dielectric constant, D , and the refractive index, n , of any substance, Maxwell obtained the relation $n = \sqrt{D\mu}$, where μ is the coefficient of magnetic induction. This coefficient in the four above mentioned substances cannot be very different from air, which is taken as $=1$. So that we have the index of refraction equal to the square root of the constant of dielectricity. M. Boltzmann accordingly compares the square roots of these constants as found by his method with the refractive indices as determined by Wollaston's method; and the differences are not sufficiently great not to be attributed to unavoidable errors of observation. He considers these results, though not so accurate as to lead to the identification of light and electricity, yet furnish strong support to Maxwell's theory.

Stroboscopic Determination of the Pitch of Tones.—M. Mach.—In the apparatus used by the author there is a cylinder which makes three revolutions in a second, and is divided into five octaves. At one end of it begins 10 bands, which, however, become more numerous and dense towards the other end, being there 320. To the axis of a syren is fixed a disc having equidistant radial slits of the same number as the holes in the syren-disc. The surface of the rotating cylinder is looked at through this slitted disc, while the syren tone is gradually raised. According to the stroboscopic principle the bands look distinct and at rest where there pass before the eye an equal number of them and of slits in the disc. If a scale of numbers of vibration be attached to the cylinder, the number of vibrations of the syren can be at once ascertained by observing the part corresponding to the distinct and still ring of the cylinder. One sees, however, distinct and at rest, not only the part of the cylinder corresponding to the number of vibrations of the syren, but also all those parts which correspond to the harmonic over tones. Of all such parts it is, of course, that one which furnishes the smallest number of vibrations that corresponds to the vibration-number of the syren. (The author gives further details of the apparatus.) The determination may be varied in accuracy by varying the bands on the paper of the rotating cylinder. The apparatus may be applied to other sounding bodies. Thus let a mono-chord string be stretched at right angles to the axis of the cylinder; then simple teeth (Zachen) appear where the sounding string is opposite that part of the cylinder indicating the same

number of vibrations. Another application is to attach small mirrors to tuning-forks, and watch in them the image of the rotating cylinder. An organ pipe may be also submitted to observation with aid of König's capsules and dancing jets.

Heat Equilibrium among Gas Molecules.—Boltzmann.—A lengthy mathematico-physical paper, treating the subject under the six heads of—(1) Consideration of one-atomed gas molecules; (2) replacement of integrals with sums; (3) diffusion, friction, and conduction of heat in gases; (4) consideration of several-atomed molecules; (5) the molecules do not make many vibrations between one collision and the next; (6) solution of equation and calculation of eutrophy.

Chemical Guide to the Vienna Exhibition.—A. Bauer and J. Stingl.—A translation from the *Transactions* of the Berlin Chemical Society.

Determination of Paraffin in Candles sold as Stearin.—E. Donath.—M. Hock had proposed to saponify the sample to be examined with a soda lye, and to salt out the soap formed by an addition of common salt. This precipitate carries down with it the paraffin, which of course has not been saponified by the alkali. The whole is collected on a filter, washed with water, or with very dilute alcohol, which dissolves out the soap, and dried at 35° to 40°. The paraffin is then dissolved in ether, and the solution evaporated to dryness. The weight of the residue shows the amount of paraffin. Donath having tried this method finds that it is very difficult to remove the soap from the filter in the cold by washing with water or dilute alcohol, whilst if the solvent be applied hot, or even slightly warmed, the paraffin forms an emulsion and runs through the filter. The solution of paraffin in ether is also a slow process. Hence Donath proposes the following modification:—6 grms. of the sample are boiled for half-an-hour with 200 to 300 c.c. of potash-lye, specific gravity, 1.15, and chloride of calcium is then added so as to produce a complete precipitation. If a large admixture of paraffin is suspected a quantity of carbonate of soda is added to the chloride of calcium, which gives rise to the formation of carbonate of lime, and renders the precipitate more easy to pulverise. The lime-soap with which the paraffin is mechanically entangled is washed on the filter with hot water and dried at 100°. The mass is then pulverised and exhausted in a displacement apparatus with cerosolin (essence of petroleum). The solution obtained is evaporated, and the residue after being dried at 100° is weighed as paraffin. On operating upon known mixtures the author has obtained results correct to 0.3 per cent.

Determinations of Acids in Oils.—M. Burstynn.—To 100 c.c. of the oil in question the author adds an equal volume of alcohol at 90 per cent and shakes strongly. The whole is then left to settle for some hours, when two layers are formed. The one is oil perfectly free from acid,

the other consists of alcohol containing the fatty acids and a trace of oil. Of this latter portion 20 c.c. are taken and titrated with a standard solution of soda. If several free fatty acids are present, the calculation is made for one only, employing the equivalent of the one present in the largest proportion. The results obtained are sufficiently accurate for practical purposes.

Adulteration of Wax with Tallow.—M. Hardy.—Wax floats upon alcohol at 29°. By determining the strength which alcohol must have so that the sample may float upon its surface, the quantity of wax may be found in a sample falsified with tallow only:—

When the Alcoholometer marks—	The Wax contains—
29°00'	100 per cent
39°63'	75 "
50°25'	50 "
60°87'	25 "
71°50'	0 "

Determination of Manganese in Cast-Irons and Steels.—F. Kiesser.—One of the main causes of the loss of manganese in these determinations springs from the employment of too large an amount of acetate of soda in the previous precipitation of the iron. The author finds that in a perfectly neutral solution 1 grm. acetate of soda suffices to precipitate completely 1.1 grm. of iron in 500 c.c. of solution, and even in presence of 1 grm. of acetic acid. When the determination of the manganese alone is required, he cools the liquid, makes up its volume to 500 c.c., filters through a dry filter, and determines the manganese in 250 c.c.

Definition of Explosive Force.—M. R. Radau.—A mathematical paper on the measurement of the force of explosive bodies.

Means of Comparing Samples of Gunpowder.—M. de Tromenic.—The apparatus proposed is a cylindrical vessel of cast steel of the capacity of half a litre. The sides are 3 to 4 centimetres in thickness. The cylinder is closed with a screw stopper pierced by a central channel provided with a tap and two lateral orifices, into which are cemented two wires from an electric apparatus to ignite the charge. It would be useful to fix a thermo-electric element in one of the sides of the cylinder to indicate the temperature of the gases in periods following the explosion. The cylinder is placed in a sheet-iron receiver full of water which serves as a calorimeter, and which is again enclosed in a trough full of cotton to avoid loss of heat. The cylinder is fixed immovably by a pressure-screw resting upon the stopper. A thermometer measures the temperature to about $\frac{1}{100}$ th of a degree. The water is provided with an agitator.

Heat of the Combustion of Explosive Bodies.—MM. Roux and Sarrau.—A mathematical paper.

Pyrometer for the Determination of High Temperatures.—J. Salleron.—The description of this instrument would be unintelligible without the accompanying diagrams.

Revue Universelle des Mines, de la Metallurgie, des Travaux Publics, des Sciences et des Arts Appliqués à l'Industrie, May and June, 1873.

Chemical Industry at the Vienna Exhibition.—This paper is a translation from the German Catalogue of the Exhibition, and is mainly due to Prof. A. W. Hofmann, of Berlin. The subjects principally treated of are the recent improvements in the manufactures of sulphuric acid, of soda, of chlorine, of potash, of paraffin, and of colouring matters. We extract the following interesting facts concerning the Stassfurt and Leopolds Hall potash works:—The chloride of potassium obtained, ranging in strength from 98 to 80 per cent, serves for the preparation of saltpetre, sulphate of potash, potash, and alum. The annual yield is about a million centners. The potassic

manurial salts are mixtures of the chloride of potassium, with different proportions of sulphate of magnesia and common salt. The annual yield is a million and a quarter centners. The production of potash and sulphate of potash amounts to fifty thousand. Sulphate of magnesia, crude and crystallised (Kieserite and Epsom salts), is obtained to the extent of a quarter of a million centners. Chloride of magnesium, crystallised and fused, 130,000 centners. Sulphate of soda, crystallised and calcined, is obtained from sulphate of magnesia and chloride of sodium by double decomposition at low temperatures, to the extent of 150,000 centners. About 400 centners of boracic acid, and 700 of bromine are also produced yearly. Since the opening of the Stassfurt mines the price of chloride of potassium has fallen from 21s. to 24s. per centner to from 7s. to 9s. Bromine up to 1865 cost 48s. to 51s. per kilo; its price is now from 9s. to 10s. 6d. The deposits of Kalnez, in Galicia, have only been worked since 1869. There are found there rich and heavy beds of sylvin and kainite; below which carnallite will probably be discovered. The section on colouring matters will give the reader cause for reflection. That England should be obliged to import 8000 cwts. of artificial alizarin yearly whilst she exports the raw material, anthracene, is simply a national disgrace. That Germany alone produces about one-half of the anilin colours consumed in the world is a fact that clashes strangely with our notions of manufacturing supremacy.

Condition of Mining in the Island of Sardinia.—M. Sella.—(Continuation.)—Ores of iron, copper, manganese, and antimony, and the lignites of the tertiary basin of Gonnesa have been worked at different times, but without success. Iron ores are tolerably abundant, especially the magnetic protoxide, which is found in veins and masses in the granite and the superjacent Silurian schists. Hematite is found in the trachytic formation. The principal copper ore is chalcopryite, found in the argillaceous schists of the Silurian regions. Some fine specimens of sulphide of antimony have been found at Su Suergin, in the centre of the island, accompanied by an argillaceous gangue. Pyrolusite is found to a considerable extent at Capo Rosso, on the western coast, but of low quality. At Flumini-maggiore occurs an ore of nickel and cobalt, yielding 20 per cent of the two metals. The difficulty of transport, and the distance from a market, render many of the Sardinian mineral deposits practically worthless.

MISCELLANEOUS.

The American Association for the Advancement of Science.—This Association held its twenty-second annual meeting at Portland, Maine, beginning Wednesday, August 20th. The Officers of the meeting are as follows:—President, Prof. Joseph Lovering, of Cambridge, Mass.; Vice-President, A. H. Worthen; Permanent Secretary, F. W. Putnam; General Secretary, C. A. White. The attendance of members was large, and a goodly number of papers were presented. Strictly chemical papers, however, were few, the deficiency being even more marked than usual. The titles of the papers on chemical and closely related subjects are as follows:—"On the Silt Analysis of Soils and Clays," E. W. Hilgard; "Analysis of Mississippi Soils and Subsoils," E. W. Hilgard; "On the Distribution of Soil Ingredients in the Sediments obtained by Silt Analysis," R. H. Loughbridge; "On the Influence of Strength of Acid, and Time of Action on the Results of Chemical Soil Analysis," R. H. Loughbridge; "Remarks on Plate Lime-Glass and the Manufacture of Glass in General," L. Feuchtwanger; "The Chemistry of Copper Matte," T. Sterry Hunt; "Metaphysical Theory of Chemistry versus the Atomic," Clinton Roosevelt. As in former years subjects connected with geology and natural history formed the bulk of the papers.

THE CHEMICAL NEWS.

VOL. XXVIII. No. 722.

BRITISH ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE.

BRADFORD MEETING, SEPTEMBER 17, 1873.

INAUGURAL ADDRESS OF THE PRESIDENT,
ALEXANDER W. WILLIAMSON, PH.D., F.R.S., F.C.S.

(Concluded from p. 148).

I TRUST that the facts which I have submitted to your consideration may suffice to show you how fallacious is that materialistic idea of Physical Science which represents it as leading away from the study of man's noblest faculties, and from a sympathy with his most elevated aspirations, towards mere inanimate matter. The material work of science is directed by ideas towards the attainment of further ideas. Each step in science is an addition to our ideas, or an improvement of them. A science is but a body of ideas respecting the order of nature.

Each idea which forms part of Physical Science has been derived from observation of nature, and has been tested again and again in the most various ways by reference to nature; but this very soundness of our materials enables us to raise upon the rock of truth a loftier structure of ideas than could be erected on any other foundation by the aid of uncertain materials.

The study of science is the study of man's most accurate and perfect intellectual labours; and he who would know the powers of the human mind must go to science for his materials.

Like other powers of the mind, the imagination is powerfully exercised, and at the same time disciplined, by scientific work. Every investigator has frequent occasion to call forth in his mind a distinct image of something in nature which could produce the appearances which he witnesses, or to frame a proposition embodying some observed relation; and in each case the image or the proposition is required to be true to the materials from which it is formed. There is, perhaps, no more perfect elementary illustration of the accurate and useful employment of the imagination than the process of forming in the language of symbols, from concrete data, one of those admirable general propositions called equations; on the other hand, the contemplation of the order and harmony of nature as disclosed to us by science supplies the imagination with materials of surpassing grandeur and brilliancy, while at the same time affording the widest scope for its efforts.

The foregoing considerations respecting the meaning and use of scientific work will, I trust, afford us aid in considering what measures ought to be taken in order to promote its advancement, and what we can do to further the adoption of such measures.

Like any other natural phenomenon, the growth of knowledge in the human mind is favoured and promoted by certain circumstances, impeded or arrested by others; and it is for us to ascertain from experience what those circumstances respectively are, and how the favourable ones can be best combined to the exclusion of the others.

The best and noblest things in this world are the result of gradual growth, by the free action of natural forces; and the proper function of legislation is to systematise the conditions most favourable to the free action which is desired.

I shall consider the words "Advancement of Science" as referring to the development and extension of our systematic knowledge of natural phenomena by investigation and research.

The first thing wanted for the work of advancing science is a supply of well-qualified workers. The second thing is to place and keep them under the conditions most favourable to their efficient activity. The most suitable men must be found while still young, and trained to the work. Now I know only one really effectual way of finding the youths who are best endowed by nature for the purpose; and that is to systematise and develop the natural conditions which accidentally concur in particular cases, and enable youths to rise from the crowd.

The first of these is that a young man gets a desire for knowledge by seeing the value and beauty of some which he has acquired. When he has got this desire, he exerts himself to increase his store; and every difficulty surmounted increases his love of the pursuit, and strengthens his determination to go on. His exertions are seen by some more experienced man, who helps him to place himself under circumstances favourable to further progress. He then has opportunities of seeing original inquiries conducted, perhaps even of aiding in them; and he longs to prove that he also can work out new truths, and make some permanent addition to human knowledge. If his circumstances enable him to prosecute such work, and he succeeds in making some new observations worthy of publication, he is at once known by them to the community of scientific men, and employed among them.

We want, then, a system which shall give to the young favourable opportunities of acquiring a clear and, as far as it goes, a thorough knowledge of some few truths of nature such as they can understand and enjoy—which shall afford opportunity of further and further instruction to those who have best profited by that which has been given to them, and are anxious to obtain more—which shall enable the best students to see what original investigation is, and, if possible, to assist in carrying out some research—and, finally, which shall supply to each student who has the power and the will to conduct researches, all material conditions which are requisite for the purpose.

But investigators, once found, ought to be placed in the circumstances most favourable to their efficient activity.

The first and most fundamental condition for this is, that their desire for the acquisition of knowledge be kept alive and fostered. They must not merely retain the hold which they have acquired on the general body of their science; they ought to strengthen and extend that hold, by acquiring a more complete and accurate knowledge of its doctrines and methods; in a word, they ought to be more thorough students than during their state of preliminary training.

They must be able to live by their work, without diverting any of their energies to other pursuits; and they must feel security against want, in the event of illness or in their old age.

They must be supplied with intelligent and trained assistants to aid in the conduct of their researches, and whatever buildings, apparatus, and materials may be required for conducting those researches effectively.

The desired system must therefore provide arrangements favourable to the maintenance and development of the true student spirit in investigators, while providing them with permanent means of subsistence, sufficient to enable them to feel secure and tranquil in working at science alone, yet not sufficient to neutralise their motives for exertion; and at the same time it must give them all external aids, in proportion to their wants and powers of making good use of them.

Now I propose to describe the outlines of such a system, framed for the sole purpose of promoting research, and then to consider what other results would follow from its working.

If it should appear possible to establish a system for the

efficient advancement of science, which would be productive of direct good to the community in other important ways, I think you will agree with me that we ought to do all that we can to promote its adoption.

Let the most intelligent and studious children from every primary school be sent, free of expense, to the most accessible secondary school for one year; let the best of these be selected and allowed to continue for a second year, and so on, until the *élite* of them have learnt all that is to be there learnt to advantage. Let the best pupils from the secondary schools be sent to a college of their own selection, and there subjected to a similar process of annual weeding; and, finally, let those who get satisfactorily to the end of a college curriculum be supplied with an allowance sufficient for their maintenance for a year, on condition of their devoting their undivided energies to research, under the inspection of competent college authorities, while allowed such aids and facilities as the college can supply, with the addition of money-grants for special purposes. Let all who do well during this first year be allowed similar advantages for a second, and even a third year.

Each young investigator thus trained must exert himself to obtain some appointment, which may enable him to do the most useful and creditable work of which he is capable, while combining the conditions most favourable to his own improvement.

Let there be in every college as many Professorships and Assistantships in each branch of science as are needed for the efficient conduct of the work there going on, and let every Professor and Assistant have such salary and such funds for apparatus, &c., as may enable him to devote all his powers to the duties of his post, under conditions favourable to the success of those duties; but let each Professor receive also a proportion of the fees paid by his pupils, so that it may be his direct interest to do his work with the utmost attainable efficiency, and attract more pupils.

Let every college and school be governed by an independent body of men, striving to increase its usefulness and reputation, by sympathy with the labours of the working staff, by material aid to them when needed, and by getting the very best man they can, from their own or any other college, to supply each vacancy as it arises.

In addition to colleges, which are and always have been the chief institutions for the advancement of learning, establishments for the observation of special phenomena are frequently needed, and will doubtless be found desirable in aid of a general system for the advancement of science.

Now, if a system fulfilling the conditions which I have thus briefly sketched out were once properly established on a sufficient scale, it ought to develop and improve itself by the very process of its working; and it behoves us, in judging of the system, to consider how such development and improvement would come about.

The thing most needed at the present time for the advancement of science is a supply of teachers devoted to that object—men so earnestly striving for more knowledge and better knowledge as to be model students, stimulating and encouraging those around them by their example as much as by their teaching. Young men do not prepare themselves in any numbers for such a career:—

(1). Because the chief influences which surround them at school and at college are not calculated to awaken in them a desire to obtain excellence of such kind.

(2). Because they could not expect by means of such qualities to reach a position which would afford a competent subsistence.

Let these conditions be reversed, to the extent that existing teachers have powerful inducements to make their students love the study of science for its own sake, with just confidence that they will be able to earn a livelihood if they succeed in qualifying themselves to advance science, and the whole thing is changed. The first batch of young investigators will be dispersed among schools and colleges

according to their powers and acquirements, and will at once improve their influence upon the pupils, and enable them to send up a second batch better trained than the first. This improvement will go on increasing, if the natural forces which promote it are allowed free play; and the youth of each successive generation will have better and more frequent opportunities of awakening to a love of learning, better help and guidance in their efforts to acquire and use the glorious inheritance of knowledge which had been left them, better and more numerous living examples of men devoting their whole lives to the extension of the domain of truth, and seeking their highest reward in the consciousness that their exertions have benefited their fellow men, and are appreciated by them.

A young man who is duly qualified for the work of teaching the investigation of some particular branch of science, and who wishes to devote himself to it, will become a member of an association of men selected for their known devotion to learning, and for their ability to teach the methods of investigation in their respective subjects. Around this central group is arranged a frequently changing body of youths, who trust to them for encouragement and guidance in their respective studies.

Our young investigator finds it necessary to study again more carefully many parts of his subject, and to examine accurately the evidence of various conclusions which he had formerly adopted, in order that he may be able to lead the minds of his pupils by easy and natural, yet secure, steps to the discovery of the general truths which are within their reach. He goes over his branch of science again and again from the foundation upwards, striving each time to present its essential particulars more clearly and more forcibly, arranging them in the order best calculated to stimulate an inquiring mind to reflect upon their meaning, and to direct its efforts effectively to the discovery of the general ideas which are to be derived from them. He is encouraged in these efforts by the sympathy of his colleagues, and often aided by suggestions derived from their experience in teaching other branches of science, or by information respecting doctrines or methods which throw a light upon those of his own subject.

No known conditions are so well calculated to give a young investigator the closest and strongest grasp of his subject of which he is capable as those in which he is placed while thus earnestly teaching it in a college; and inasmuch as a thorough mastery of known truths is needed by every one who would work to advantage at the discovery of new truths of that kind, it will, in most cases, be an object of ambition to the ablest young investigators to get an opportunity of going through the work of teaching in a college, in order to improve themselves to the utmost for the work of original research. There is, however, another advantage to them in having such work to do; for the best way to ascertain at any one time what additions may be made to a science, is to examine the facts which have been discovered last, and to consider how far they confirm and extend the established ideas of the science, how far they militate against those ideas. An investigating teacher is constantly weaving new facts into the body of his science, and forming anticipations of new truths by considering the relation of these new facts to the old ones.

When our investigator has thus got a thorough mastery of his science and new ideas for its extension, he ought to have the opportunity of turning his improved powers to account by devoting more of his time to original research; in fact he ought to teach research by example more than hitherto, and less by elementary exercises upon known facts. If he has discharged the duties of his first post with manifest efficiency, he will be promoted, either in his own or some other college, to a chair affording more leisure and facility for original research by his own hands and by those of his assistants and pupils. Some investigators may find it desirable to give up after a while all teaching

of previously published truths, and confine themselves to guiding the original researches of advanced pupils, while stimulating them by the example of their own discoveries. But most of them will probably prefer to do elementary teaching work from time to time, for the sake of the opportunity of going over the groundwork of their science, with a knowledge of the new facts and enlarged ideas recently established.

Now it must be observed that such a system as the above, once developed to its proper proportions, so as to send annually to secondary schools many thousands of poor children who would otherwise never enjoy such advantages, and so as to train to original investigation a corresponding proportion of them, would not only provide more young investigators than would be needed for systematic teaching functions, but would also give a partial training of the same kind to many whose abilities proved to be insufficient, or whose tastes were not congenial to such pursuit. Some would be tempted by an advantageous opening in an industrial pursuit or in the public service to break off their studies before completion, and others would find, after completing their training, a position of that kind more desirable or more attainable than a purely scientific appointment. Not only would much good of other kinds be accomplished by this circumstance, but we may say with confidence that the system could not work with full advantage for its own special purpose of promoting the advancement of science if it did not diffuse a knowledge of the truths and methods of science beyond the circle of teachers.

There is an urgent need of accurate scientific knowledge for the direction of manufacturing processes, and there could not be a greater mistake than to suppose that such knowledge need not go beyond the elementary truths of science. In every branch of manufacture improvements are made from time to time, by the introduction of new or modified processes which had been discovered by means of investigations as arduous as those conducted for purely scientific purposes, and involving as great powers and accomplishments on the part of those who conducted them.

Any manufacturer of the present day who does not make efficient arrangements for gradually perfecting and improving his processes ought to make at once enough money to retire; for so many are moving onwards in this and other countries, that he would soon be left behind.

It would be well worth while to establish such a system of scientific education for the sake of training men to the habits of mind which are required for the improvement of the manufacturing arts; and I have no doubt that the expense of working the system would be repaid a hundred times over by the increase of wealth of the community; but I only mention this as a secondary advantage of national education.

A system of the kind could not expand to due dimensions, nor could it, once fully established, maintain itself in full activity, without intelligent sympathy from the community; and accordingly its more active-minded members must be taught some good examples of the processes and results of scientific inquiry, before they can be expected to take much interest in the results achieved by inquirers, and to do their share of the work requisite for the success of the system. I need hardly remind you that there are plenty of other strong reasons why some such knowledge of the truths of nature, and of the means by which they are found out, should be diffused as widely as possible throughout the community.

You perceive that in such educational system each teacher must trust to his own exertions for success and advancement; and he will do so if he is sure that his results will be known and compared impartially with those attained by others. Each governing body must duly maintain the efficiency of their school or college, if its support depend in some degree on the evidences of that efficiency; and they will try to improve their school

if they know that every improvement will be seen and duly appreciated.

The key-stone of the whole structure is the action of the State in distributing funds carefully among schools and colleges proportionally to the evidence of their doing good work, which could not be continued without such aid.

I am inclined to think that the State ought, as far as possible, to confine its educational grants to the purpose of maintaining and continuing good work which is actually being done, and rarely, if ever, to initiate educational experiments: first, because it is desirable to encourage private exertions and donations for the establishment of schools and colleges upon new systems, or in new localities, by giving the public full assurance that if any new institution establishes its right to existence, by doing good work for a while, it will not be allowed to die off for want of support; and, secondly, because the judicial impartiality required in the administration of public funds, on the basis of results of work, is hardly compatible with an advocacy of any particular means of attaining such results.

On the other hand, experience has shown that special endowments, which tie up funds in perpetuity for a definite purpose, commonly fail to attain their object under the altered circumstances which spring up in later generations, and not unfrequently detract from the efficiency of the institutions to which they are attached, by being used for objects other than those which it is their proper function to promote.

When there is felt to be a real want of any new institution for the promotion of learning, men are usually willing enough to devote time and money to the purpose of establishing it and giving it a fair trial. It is desirable that they should leave the State to judge of their experiment by its results, and to maintain it or not, according to the evidence of its usefulness. No institution ought, for its own sake, to have such permanent endowments as might deprive its members of motives for exertion.

The State could not, however, discharge these judicial functions without accurate and trustworthy evidence of the educational work done at the various schools and of its success. For this purpose a record must be kept by or under the direction of every teacher of the weekly progress of each pupil, showing what he has done and how he has done it. Official inspectors would have to see to these records being kept upon a uniform scale, so that their results might be comparable. The habit of keeping such records conduces powerfully to the efficiency of teachers; and, for the sake of the due development of the teaching system, it ought to prevail generally. Having such full and accurate means of knowing what opportunities of improvement pupils have enjoyed, and what use they have made of those opportunities, Government ought to stimulate their exertions and test their progress by periodical examinations. It is of the utmost importance to allow any new and improved system of instruction to develop itself freely, by the exertions of those who are willing to undertake the labour and risk of trying it on a practical scale; and the pupils who acquire upon such new system a command of any branch of science, ought to have a fair opportunity of showing what they have achieved and how they have achieved it. An able and impartial examiner, knowing the new systems in use, will encourage each candidate to work out his results in the manner in which he has been taught to work out results of the kind.

Examinations thus impartially conducted with a view of testing the success of teachers in the work which they are endeavouring to do, have a far higher value, and consequent authority, than those which are conducted in ignorance or disregard of the process of training to which the candidates have been subjected; and we may safely say that the examination system will not attain its full usefulness until it is thus worked in intimate connection with a system of teaching.

In order to give every one employed in the educational system the utmost interest in maintaining and increasing

his efficiency, it is essential that a due measure of publicity be given to the chief results of their respective labours. Schools and colleges ought, to a considerable extent, to be supported by the fees paid by pupils for the instruction received; and every professor being in part dependent upon the fees of his pupils will have a direct interest in attracting more pupils to his classes or laboratories. The fame of important original investigations of his own or his pupils, published in the scientific journals, is one of the natural means by which a distinguished professor attracts disciples, and the success of his pupils in after life is another. His prospects of promotion will depend mainly on the opinion formed of his powers from such materials as these by the governing bodies of colleges and by the public; for if each college is dependent for success upon the efficiency of its teaching staff, its governing body must do their best to fill up every vacancy as it arises by the appointment of the ablest and most successful professor whom they can get; and any college which does not succeed in obtaining the services of able men will soon lose reputation, and fall off in numbers.

There are, however, further advantages to the working of the system to be derived from full publicity of all its more important proceedings. It will supply materials for the formation of a sound public opinion respecting the proceedings of the authorities in their various spheres of action. A claim for money might be made upon Government by the rulers of some college upon inadequate grounds; or a just and proper claim of the kind might be disregarded by Government. Neither of these things will be likely to happen very often if the applications, together with the evidence bearing on them, are open to public scrutiny and criticism; and when they do occasionally happen, there will be a natural remedy for them.

If I have succeeded in making clear to you the leading principles of the plan to be adopted for the advancement of science, including, as it necessarily must do, national education generally, you will, I think, agree with me that, from the very magnitude and variety of the interests involved in its action, such system must of necessity be under the supreme control of Government. Science will never take its proper place among the chief elements of national greatness and advancement until it is acknowledged as such by that embodiment of the national will which we call the Government. Nor can the various institutions for its advancement develop duly their usefulness until the chaos in which they are now plunged gives place to such order as it is the proper function of Government to establish and maintain.

But Government has already taken, and is continuing to take, action in various matters affecting elementary popular education and higher scientific education, and it would be difficult to arrest such action, even if it were thought desirable to do so. The only practical question to be considered is how the action of Government can be systematised so as to give free play to the natural forces which have to do the work.

By establishing official examinations for appointments and for degrees, Government exerts a powerful influence on the teaching in schools and colleges, without taking cognisance, except in some few cases, of the systems of teaching which prevail in them. Again, they give grants of public money from time to time in aid of colleges or universities, or for the establishment of a high school under their own auspices. Sometimes they endow a professorship. In taking each measure of the kind they are doubtless influenced by evidence that it is in itself a good thing, calculated to promote the advancement of learning. But a thing which is good in itself may produce evil effects in relation to others, or good effects incommensurate with its cost. Thus examinations afford most valuable aid to educational work when carried on in conjunction with earnest teachers; yet, when established in the absence of a good system of education, they are liable to give rise to a one-sided training contrived with a special view of getting young men through the examinations, if

no properly educated young men were found for a particular department of the public service, and an examination of all candidates for such appointments were to be established for the purpose of improving the system of training, candidates would consider their power of answering such questions as appeared likely to be set as the condition of their obtaining the appointments, and they would look out for men able and willing to train them to that particular work in as direct and effective a manner as possible. The demand for such instruction would soon be supplied. Some teachers would undertake to give instruction for the mere purpose of enabling candidates to get through the examination, and, by the continued habit of such work, would gradually come to look upon the examiners as malignant beings who keep youths out of office, and whose vigilance ought to be evaded by such means as experience might show to be most effective for the purpose. Once this kind of direct examination-teaching has taken root, and is known to produce the desired effect of getting young men through the examinations, its existence encourages the tendency on the part of the candidates to look merely to the examination as the end and aim of their study; and a class of teachers is developed whose exertions are essentially antagonistic to those of the examiners.

There are, no doubt, teachers with a sufficiently clear apprehension of their duty, and sufficient authority, to convince some of the candidates that the proper object of their study should be to increase their power of usefulness in the career for which they are preparing themselves, by thoroughly mastering up to a prescribed point certain branches of knowledge; and that, until they had honestly taken the means to do this, and believed they had done it effectually, they ought not to go up for examination, nor to wish to commence their career.

But it is desirable that all teachers be placed under such circumstances that it may become their interest as well as their duty to co-operate to the utmost of their powers in the object for which the examiners are working. For this purpose their records of the work done under their guidance by each pupil ought to be carefully inspected by the examiners before framing their questions, and ought to be accepted as affording the chief evidence of the respective merits of the pupils.

This is not the place for considering how the general funds for an effective system of national education can best be raised, nor how existing educational endowments can best be used in aid of those funds. It is well known that some colleges of Oxford and Cambridge are possessed of rich endowments, and that many distinguished members of those universities are desirous that the annual proceeds of those endowments should be distributed upon some system better calculated to promote the advancement of learning than that which generally prevails. Indeed we may confidently hope that, true to their glorious traditions, those colleges will be led, by the high-minded and enlightened counsels of their members, to rely upon improving usefulness in the advancement of learning as the only secure and worthy basis of their action in the use of their funds, so that they may take a leading part in such system of national education as may be moulded out of the present chaos.

But the foundations of a national system of education ought to be laid independently of the present arrangements at Oxford and Cambridge, for we may be sure that the more progress the system makes the more easy will become the necessary reforms in the older universities and colleges.

It is clearly undesirable that Government should longer delay obtaining such full and accurate knowledge of the existing national resources for educational purposes, and of the manner in which they are respectively utilised, as may enable them to judge of the comparative prospects of usefulness presented by the various modes of distributing educational grants. They ought to know what has been done and what is doing in the various public educational

establishments before they can judge which of them would be likely to make the best use of a grant of public money.

We have official authority for expecting such impartial administration of educational grants; and it cannot be doubted that before long due means will be taken to supply the preliminary conditions.

You are no doubt aware that a Royal Commission was appointed some time ago in consequence of representations made to Government by the British Association on this subject, and it is understood that their instructions are so framed as to direct their particular attention to the manner in which Government may best distribute educational grants. The Commission is moreover composed of most distinguished men, and we have every reason to anticipate from their labours a result worthy of the nation and of the momentous occasion.

In speaking of public educational establishments, I refer to those which by their constitution are devoted to the advancement of learning without pecuniary profit to their respective governing bodies. The annual expenditure requisite for keeping up a national system of popular education will necessarily be considerable from the first, and will become greater from year to year; but once Englishmen are fully alive to the paramount importance of the object, and see that its attainment is within their reach, we may be sure that its expense will be no impediment. England would not deserve to reap the glorious fruits of the harvest of knowledge if she grudged the necessary outlay for seed and tillage, were it even ten times greater than it will be. It is no use attempting to establish a national system on any other than a truly national basis. Private and corporate funds inevitably get diverted from popular use, after a few generations, to the use of the influential and rich. A national system must steadily keep in view the improvement of the poor, and distribute public funds each year in the manner best calculated to give the youths of the poorest classes full opportunities of improvement proportional to their capacities, so that they may qualify themselves for the utmost usefulness to their country of which they are capable. The best possible security for the proper administration of the system will be found in the full and speedy publicity of all the particulars of its working.

It has been frequently remarked that a great proportion of English investigators are men of independent means, who not only seek no advancement as a reward of their labours, but often sacrifice those opportunities of improving their worldly position which their abilities and influence open up to them, for the sake of quietly advancing human knowledge. Rich and powerful men have very great temptations to turn away from science, so that those who devote their time and money to its service prove to us how true and pure a love of science exists in this country, and how Englishmen will cultivate it when it is in their power to do so.

Now and then a youth from the poorer classes is enabled by fortunate accidents and the aid of a friendly hand to climb to a position of scientific activity, and to give us, as Faraday did, a sample of the intellectual powers which lie fallow in the great mass of the people.

Now, the practical conclusion to which I want to lead you is, that it rests with you, who represent the national desire for the advancement of science, to take the only measures which can now be taken towards the establishment of a system of education worthy of this country, and adapted to the requirements of science. In the present stage of the business the first thing to be done is to arouse public attention by all practicable means to the importance of the want, and to get people gradually to agree to some definite and practicable plan of action. You will, I think, find that the best way to promote such agreement is to make people consider the natural forces which have to be systematised by legislation, with a view of enabling them to work freely for the desired purpose. When the conditions essential to any national system come to be duly appreciated by those interested in the

cause of education, means will soon be found to carry out the necessary legislative enactments.

The highest offices in the State are on our present system filled by men who, whatever their political opinions and party ties, almost infallibly agree in their disinterested desire to signalise their respective terms of office by doing any good in their power. Convince them that a measure desired by the leaders of public opinion is in itself good and useful, and you are sure to carry it.

And, on the other hand, England is not wanting in men both able and willing to come forward as the champions of any great cause, and to devote their best powers to its service.

I may well say this at Bradford after the results achieved by your Member in the Elementary Education Act.

Objections will, of course, be raised to any system on the score of difficulty and expense, more especially to a complete and good system. Difficult of realisation it certainly must be, for it will need the devoted and indefatigable exertions of many an able and high-minded man for many a long year. Only show how such exertions can be made to produce great and abiding results, and they will not be wanting. And as for expense, you will surely agree with me that the more money is distributed in such frugal and effective manner, the better for the real greatness of our country.

What nobler privilege is attached to the possession of money than that of doing good to our fellow men? and who would grudge giving freely from his surplus, or even depriving himself of some comforts, for the sake of preparing the rising generation for a life of the utmost usefulness and consequent happiness?

I confidently trust that the time will come when the chief item in the annual budget of the Chancellor of the Exchequer will be the vote for National Education; and when in some later age our nation shall have passed away, when a more true civilisation has grown up and has formed new centres for its throbbing life, when there are but broken arches to tell of our bridges and crumbling ruins to mark the sites of our great cathedrals—then will the greatest and noblest of England's works stand more perfect and more beautiful than ever; then will some man survey the results of Old England's labours in the discovery of imperishable truths and laws of nature, and see that her energy and wealth were accompanied by some nobler attributes—that while Englishmen were strong and ambitious enough to grasp power, they were true enough to use it for its only worthy purpose, that of doing good to others.

I must not, however, trespass longer upon your time and your kind attention. My subject would carry me on, yet I must stop without having half done justice to it.

If I have succeeded in convincing you that a National system of Education is now necessary and possible, and in persuading you to do what you respectively can to prepare the way for it, I shall feel that the first step is made towards that great result.

SECTION B.—CHEMICAL SCIENCE.

For the benefit of those of our readers who were prevented from attending the 1873 meeting of the Association we print short abstracts of the papers read before the Chemical Section, with a condensed report of the discussions. Those papers which are of sufficient importance will be inserted in full as quickly as our space will permit.

"*Report on the Chemical Constitution and Optical Properties of Essential Oils.*"—The report consisted of a *resumé* of the results obtained during the previous year's work, in continuation of the work described in previous reports. The products of the actions of hitric acid on hesperidin, and the terpen present in oil of nutmegs (hesperic and myristic acids, &c.), were described, the conclusion drawn being that oil of turpentine, oil of nutmegs, and hesperidin are the different isomerides: some

probable inferences were also made as to the connections between the nature of isomerism and the *intrinsic chemical energy* of the different isomerides severally. The action of bromine on the oil of nutmeg and on hesperidin is the same as that on turpentine—namely, combination, the resulting dibromide being split up by heat into hydrobromic acid and cymen. The two varieties of cymen thus obtained were carefully compared with cymen from other sources—namely, the action of zinc chloride on myristic oil; the action of heat on the product of the action of phosphorus pentachloride on myristic oil, and that of phosphorus pentachloride on camphor; also with the cymen isolated from oil of turpentine and from crude nutmeg terpen; the terpen present by sulphuric acid, and that from oil of cummin. All these gave the same results on oxidation (terephthalic acid and acetic acid free from other products), had the same boiling-point (close to 176.5 in each case), and had the sp. gr. 0.860, the specific dispersion 0.0405, and the refraction equivalent 75.0, and from this it is inferred that there is but one kind of cymen as yet known, and not two, as supposed by some chemists. The oil of citronella has also been partially examined; it consists essentially of a substance having the composition of $C_{10}H_{18}O$; by the action of dehydrating agents it splits up into water and a terpen $C_{10}H_{16}$; and when bromine is added to it the resulting product breaks up, on heating, into water, hydrobromic acid, and cymen, apparently identical with the other samples examined.

Dr. GLADSTONE: One very interesting point that rose in this investigation was the refraction equivalent of the isomeric bodies of the composition $C_{10}H_{16}O$, when the carbon atoms combined with nearly, but not quite, two equivalents of hydrogen, or a corresponding amount of some other element. At present the evidence is in favour of these isomeric bodies not having the same influence on light, which may serve to explain the difference of their rational composition or structure.

"On Black Deposits on Metals," by J. H. GLADSTONE, F.R.S.—If a piece of metal be immersed in the solution of another metal which it can displace, the latter metal immediately makes its appearance at myriads of points in a condition that does not reflect light; but as the most favourably circumstanced crystals grow, they acquire the optical properties of the massive metal, the period at which the change takes place depending partly on the nature of the metal and partly on the rapidity of its growth. This was illustrated in the case of platinum, palladium, iridium, bismuth, antimony, gold, copper, lead, silver, thallium, zinc, and cadmium. If zinc be immersed in a solution of copper sulphate, the black deposit is first copper, then some black zinc is deposited on the copper, as first shown by Dr. Russell, then this zinc is more or less oxidised; and according to the stage arrived at in this action is the ease with which a metallic streak is obtained on pressure, and the colour of the streak.

Dr. RUSSELL asked whether Dr. Gladstone had ever obtained a black deposit of copper absolutely free from zinc.

Dr. THORPE had employed the copper zinc couple of Messrs. Gladstone and Tribe for reducing nitric acid, and found that the black deposit alone was effective; hence he concluded it contained zinc.

Dr. GLADSTONE fully admitted that practically there was always more or less zinc in the black deposit of the couple, but it might be obtained at first with no perceptible amount of that metal, and the zinc of the washed black deposit might be removed by treating it with sulphate of copper, when it would still remain black.

"On a Specific Gravity Bottle for Inflammable Liquids," by A. TRIBE, F.C.S.—This consisted in a modification of that of Regnault, the narrow neck being graduated, instead of one mark being made in it. The advantage was that an inflammable liquor, or one that gave dense or injurious fumes in the air, might be quickly poured in without observing the particular height in the neck till the stopper had been inserted. It also afforded the opportunity of

bringing the liquor to a desired temperature after it was in the bottle. Of course the value of the graduations must be determined.

"On Derivatives of Codeine and Morphine," by C. R. A. WRIGHT, D.Sc., F.C.S.—This paper was a *resumé* of results obtained during the previous year in continuation of those brought before the Association on former occasions. Morphine gives rise, by treatment with sulphuric acid, to polymerides precisely analogous to those found from codeine under similar conditions; trimorphine and tetramorphine have been isolated, but dimorphine has not yet been found. Derivatives from these bodies by the action of hydrochloric acid have been obtained and studied. The sulphomorphide of Laurent and Gerhardt is only tetramorphine sulphate. By the action of hydrochloric acid on morphine a chlorinated product is formed; by further treatment this forms apomorphine and a new body. Under the same circumstances codeine gives rise to a chlorinated base, homologous with that from morphine; the further action gives rise, not to apomorphine, but a somewhat similar body containing more of the elements of water, *i.e.*, intermediate between morphine and apomorphine. The action of zinc chloride on morphine has also been studied; the final products are apomorphine and an isomeric base of the tetra series, intermediate substances being found. The physiological properties of most of these new derivatives have been studied and some connections made out in certain cases between the composition and the physiological action.

A brief discussion followed, in which Drs. ARMSTRONG and MILLS took part.

INVESTIGATION OF THE FLUORESCENT AND ABSORPTION SPECTRA OF THE URANIUM SALTS.*

By HENRY MORTON, Ph.D.,
and H. CARRINGTON BOLTON, Ph.D.

(Continued from p. 116).

PART III.

PASSING now to the detailed discussion of the various compounds, we will take these up in alphabetical order for the convenience of reference.

Uranic Acetates.

Uranic acetate combines with acetates of the bases RO to form a very large number of double salts. Of these there have been described, up to the present time, the following, including the uranic acetate, which may be considered as the starting-point:—

To these we have added the following, which have not before been described:—

* Communicated by President Morton.

also the anhydrous uranic acetate, $U_2O_3C_4H_3O_3$, which we have prepared and studied.

It will be observed that in all of these compounds two molecules of uranic acetate combine with one molecule of the acetate of RO, except in the case of the salts of lead and of cadmium in which the ratio is 1 : 1.

Most of these salts crystallise very readily from acid solutions of equivalent weights of the mixed acetates; they vary considerably in stability, some, like the sodio-acetate, suffering no change at a temperature of $200^\circ C.$, and others, like the plumbo-uranic acetate, decomposing at $100^\circ C.$, or the argento-uranic acetate, which decomposes at 70° to $80^\circ C.$, or by exposure to sunlight.

Some crystallise out, on cooling, warm concentrated solutions, while others, as the lithium salt, are only obtained by evaporation over sulphuric acid.

On boiling solutions of these salts containing no free acid, uranates of the respective bases precipitate, and in many cases the same happens to a neutral solution on standing even in the cold.

All these salts we have prepared in a state of chemical purity, and have thoroughly examined as to their spectra of fluorescence and absorption, and have likewise studied the effects of heat in either temporarily or permanently modifying their properties in these connections.

In the course of these examinations we have recognised the existence of more than one hydrate of the same salt, which enables us to explain some of the discrepancies of authorities on this point.

Uranic Acetate (normal), $U_2O_3C_4H_3O_3 + 2HO$.

This substance fluoresces very brightly, different specimens, however, differing greatly in this respect, probably

appreciable with a strong light and wide opening to the slit of the spectroscope.

The brighter bands will show a very abrupt termination towards the more refrangible end, and shade off gradually so as to look like a series of short pieces of moulding illuminated from the violet side of the spectrum. No. 1 in Fig. 5 will give an idea of this, as well as of the positions of the various bands.

Measuring the edge of the bright bands at their upper or abrupt side, we get the following as the average of several sets of observations:—

Bands:—1.	2.	3.	4.	5.	6.	7.
37°0	43·8	51·6	60·7	70·4	80·2	90°0

The 8th band is too faint to show any definition on its edge, if it has any, and its measurement was therefore made at its brightest part, giving $90\cdot6$.

By turning the spectroscope obliquely on the bottle containing this salt, an absorption band at 107 can be distinguished with tolerable ease, but none above this can be well made out, and in fact, as regards this matter, the strongest contrast exists between the uranic acetates and its double salts. By crushing a few grains to a fine powder, with a little water, between slips of glass, we may, however, observe the absorption bands by transmitted light with reasonable facility, and then get a spectrum of a very curious character as regards the irregular spacing of its bands. No. 1 of Fig. 6 will give a good idea of this. Another noteworthy point is the very strong general absorption, which almost obliterates details of the spectrum, and makes it impossible to recognise any bands above one at about 135.

In solution this general absorption is decidedly increased, and the absorption bands are blended so that little can be done in the way of measuring them with ordinary means: we shall see, however, presently that this condition affords an important means of discrimination.

If we make a solution of the neutral acetate in water, and examine its absorption, we shall find a faint band at about 105, and some indication of one at about 117, but a very heavy general absorption over the entire region above the first-named band obliterating all variations of shade.

The addition of a little acetic or other strong acid will, however (while destroying the fluorescence of the solution), clear up its absorption spectrum in a remarkable manner, giving us such a one as is shown at No. 3 of Fig. 6, which we have reasons for regarding as the absorption spectrum of the double acetate of uranium and water. These reasons will be stated further on, when the necessary preliminary facts have been reviewed.

Anhydrous Uranic Acetate, $U_2O_3C_4H_3O_3$.

If the above normal uranic acetate is dried in a hot-water oven, at a temperature of $100^\circ C.$, for some hours, it becomes opaque, and of a lighter and purer yellow tint, and on examination is found to yield a fluorescent spectrum, the bands of which are like those

of the normal salt, but are all displaced downward in the spectrum. No. 2 of Fig. 5 will show the arrangement of these bands. The brightness of the fluorescence is very much reduced, and probably for this reason—the first and last bands could not be made out with the apparatus at present in use.

By inclosing this substance in dry powder, between slips of glass, its absorption spectrum was observed with transmitted light, and is shown at No. 2 of Fig. 6. The general absorption is, however, even greater in this than in the case of the normal uranic acetate, and

FIG. 5.

FIG. 6.

from the presence in certain cases of minute traces of foreign matter. Its solution also yields a very bright fluorescence, exceeding that of the nitrate, which is, however, decidedly reduced by the addition of a very minute quantity of alcohol, ether, glucose, or sucrose, and is destroyed by a very small amount of hydrochloric acid. The fluorescent light of the solution yields a continuous spectrum.

When examined with the spectroscope its fluorescent light emitted by the solid yields a system of eight bands. Of these the 1st and 7th are very faint, and the 8th only

thus the recognition of the higher bands is more difficult.

The Double Acetates.

The double acetates of uranium, as a class, give spectra which—while differing in a marked manner from that of the simple uranic acetate—have the most striking resemblance among themselves.

The fluorescent spectrum of the sodio-uranic acetate, shown in No. 3 of Fig. 1, is a type of a perfect double acetate spectrum, others differing from it only by lacking some of the fainter bands, and by some slight general displacement of all the bands up and down in the spectrum.

Taking the sodio-acetate, whose bands stand highest in the spectrum, as head of the list, the acetates would arrange themselves in the following order, noting for brevity simply the symbols of the distinguishing elements—Na, Li, K, Sr, Mg, Am, Zn, Rb, Il, Ba, Cd, Pb, Ca, Ni, Mn. At the same time it must be noted that between Am and Cd the progressive change is so gradual that the exact order cannot be insisted upon between any adjacent two, or even three in some cases.

The absorption spectra of the acetates, of which also that of the sodio-uranic acetate may be taken as the type, shift, as do their fluorescent spectra, marking again the very close relation which exists between these phenomena, while at the same time their independence is illustrated by the fact that in such cases as that of the bario-uranic acetate, where the fluorescence is exceedingly weak, and the cobalto-uranic acetate, where it is absent all together, the absorption spectrum is as well developed as in any other case.

All the double acetates, in fact, show their absorption spectra with very great ease, and most of the bands can be seen by simply directing the spectroscopist obliquely towards the bottle containing the salt under examination, when the apparatus is arranged for the study of the absorption bands.

Sodio-Uranic Acetate, $2(\text{U}_2\text{O}_3 \cdot \text{C}_4\text{H}_3\text{O}_3) + \text{NaO} \cdot \text{C}_4\text{H}_3\text{O}_3$.

This is the most brilliantly fluorescent of the uranic acetates, and yields a spectrum which it is easy to examine accurately, as a very narrow slit may be employed.

This spectrum differs entirely from that of the uranic acetate in several particulars. In the first place it has no abrupt or sharply defined termination to its bands, as has the simple acetate towards the more refrangible edge, and in the second place it has a decided secondary inflection of brightness on what may be called the upper flank of each band. Thus, if we were to represent these inflections of light by profiles, that of the acetate bands would be indicated by *a*, and those of the soda salt by *b* of the adjacent figure.

The positions of these bands as compared with those of the uranic acetate amounts to an upward displacement which brings them into the spaces between the others, and this, combined with their difference of character, produces a compound spectrum of singular beauty. The presence of this double spectrum reveals to us at a glance in most of the commercial uranic acetates the presence of the soda salt which is not specified on the label.

Another characteristic of the sodio-uranic acetate spectrum and of the double acetates generally, is that space corresponding to the two lowest groups or *s* is occupied by four narrow bands quite different in character from all above. This is well shown in No. 3

of Fig. 5, which represents at once the spectrum of this salt and of the hydro-uranic acetate, as we might call it, mentioned before.

The absorption spectrum of this salt is like others of its class, beautifully regular and well defined, being but little obscured by the general absorption which so often conceals the bands in other cases.

Each band is, moreover, composite in its structure, consisting of a narrow and abruptly terminated line, bordered by a much fainter shade, see No. 3, Fig. 6.

If we now examine the solution of this salt in a neutral state, we shall find exactly the same bright fluorescence, yielding a continuous spectrum and the same heavy general absorption with two obscure bands, that we noticed with the neutral uranic acetate. Moreover, if we add a strong acid, the fluorescence will be destroyed, and the spectrum cleared up exactly as with the above-named salt, and what is more, we shall find the same true for every one of the seventeen double acetates which we have so far examined. This spectrum, moreover, as regards the position and character of its bands, is not to be distinguished from that of the dry or anhydrous sodio-uranic acetate.

In their solid state all these salts yield spectra more or less different from this in the position of their bands, but in solution they are all alike, and the inference seems irresistible that we see in all of these solutions the spectrum of the same body.

The question then arises, what is this body? Before answering this, let us review some of the facts—(1) To produce this spectrum acetic acid must be added or set free by the addition of some other acid able to liberate it; (2) The spectrum produced is sensibly identical with that of the double acetate of sodium and uranium; (3) Previous experiments in freezing solutions have shown us that no change in a spectrum is to be expected from the mere act of "mechanical solution."

With these points before us it certainly seems probable that the body whose spectrum is here shown is a double acetate of uranium and water or a hydro-uranic acetate.

This, as a consequence, brings with it the conclusion that the uranic double acetates do not exist as such in solution, and as we find evidence of a parallel character in the case of the oxychlorides, sulphates, carbonates, &c., we may probably enunciate with safety the conclusion that the uranic double salts generally break up in solution into their respective "hydrates," or double salts, in which water is one of the bases. Various collateral points support this general view. Thus, the cobalt double acetate shows no fluorescence whatever, but its neutral solution fluoresces as brightly as that of the simple uranic acetate.

Many of the double acetates decompose in solution and crystallise out as separate salts.

Others, again, if neutral, precipitate as uranates until enough acetic acid is set free to hold the remainder (according to the view here proposed) as hydro-acetates.

The fact that the soda salt would have the smallest amount of inert matter in comparison with the active uranium except the supposed water salt, and has the highest position for its bands of all the acetates, should not be overlooked.

We have already noticed the effect which heat produces in displacing the fluorescent bands of the sodio-uranic acetate downwards in the spectrum. A series of careful observations showed that the absorption bands followed the same law.

The following measures of three bands will indicate the amount of this displacement:—

Bands.	3.	4.	5.
24° C. (75° F.) ..	105.4	115.8	126.6
138° C. (280° F.) ..	103.8	114.2	125.0

The solution of sodio-uranic acetate fluoresces very brightly, and yields a continuous spectrum when its light is examined with the spectroscopist.

At a temperature of 49° C. (120° F.) this fluorescence is sensibly reduced, and at 83° C. (181.4° F.) there is

hardly a trace left. The addition of small quantities of ether, alcohol, glucose, sucrose, and glycerin greatly reduce the fluorescence of this solution, and a very small amount of hydrochloric acid destroys it entirely, but the former bodies do not have any effect in clearing up the absorption spectrum, as has been before noticed with acids generally, in the case of the uranic acetate, which, indeed, we believe to be the body here concerned.

The positions of bands as observed in a number of the double acetates are given in the following tables, in which the substances are arranged in alphabetical order for convenience or reference. The distinctive part of the name only is given, and the reader will therefore supply the words "uranic acetate" after each of these prefixes:—

POSITIONS OF THE CENTRES OF ABSORPTION BANDS IN THE SPECTRA OF THE URANIC DOUBLE ACETATES.

Some special actions of certain salts require a further notice.

Thus, we found that when the magnesio-uranic acetate was allowed to crystallise in a desiccator it sometimes yielded crystals, which on exposure to a temperature of 100° lost a considerable amount of water and gave a continuous spectrum of fluorescence, and at others produced crystals which refused to part with any water at 100°, and when heated to a higher temperature lost water, but did not yield a continuous spectrum. Further investigation indicated that the first of these salts contained originally 12 atoms of water, and lost 4 atoms when dried at 100°, having, therefore, 8 atoms when it gave a continuous spectrum, and that the other salt contained originally 7 atoms of water.

These salts are still under investigation, Wertheim gives the magnesio salt 8 atoms of water (*Journal für Prakt. Chemie*, xxix., 209). Weselsky gives it 12 atoms, and says that over sulphuric acid it loses 6 atoms, changing it into the salt described by Rammelsberg in his *Kristallogr. Chemie*, supplement band, p. 142.

Further examination is needed to clear up these discrepancies, but the above observations throw some light on the subject.

The lead salt, if dried at 100°, loses 3H₂O, and ceases entirely to fluoresce; it will, however, dissolve in water,

but unless a little acid is added soon deposits plumbic uranate.

The lithium salt, however, by drying at 100° C., loses 3 atoms or half its water, but has its fluorescence strengthened thereby.

A specimen of strontio-uranic acetate dried at 100°, acted like the magnesium salt before mentioned, i.e., lost water and gave a continuous spectrum.

The zinc acetate, by drying at 100° C., loses CHO, and acquires a spectrum exceedingly like that of the normal uranic acetate, though the bands are broader. It may therefore, perhaps, decompose and form that salt and zinc acetate, the latter losing all its water. It is, however, curious that the uranic acetate should retain its water, as it here seems to even when heated to 150°.

(To be continued.)

ON THE CHLORINATION AND IODINATION OF ANTHRACEN.

By THOMAS BOLAS.

Action of Antimony Pentachloride and Excess of Chlorine on Anthracen.

ONE part of anthracen and three parts of powdered antimony were placed in a retort and exposed to the action of a slow stream of chlorine. When the antimony was converted into pentachloride heat was applied, and the mixture was made to boil, chlorine being still passed into it. This digestion was continued for several days, it being at first intended to continue the chlorination until the evolution of hydrochloric acid ceased; but as this gas was set free, in small quantities, long after the principal reaction had evidently terminated, the digestion was finally stopped, and the contents of the retort were treated with dilute hydrochloric acid. The portion which remained undissolved was found to be very much carbonised and to present the appearance of fragments of spongy charcoal, but on subjecting it to dry distillation a sublimate was obtained which presented a crystalline appearance. This partially dissolved in hot benzene, and the solution deposited crystalline crusts on cooling: these crusts—after one, two, and three crystallisations from benzene—melted at 236°, 247°, and 252° respectively. As the yield of this substance was but small, there appeared no prospect of obtaining it in a pure state without first chlorinating a considerable quantity of anthracen. Consequently this body remains at present for further investigation. The portion of the crude sublimed product which did not dissolve in hot benzene proved to be almost insoluble in boiling acetic acid, but it yielded, on sublimation, beautiful yellowish needles resembling sublimed anthracinon. These needles melted at a temperature above 330°, and they were found to be almost insoluble in alcohol, benzene, ligroin, and carbon tetrachloride. The amount of chlorine contained in these crystals corresponded approximately with the formula C₁₄Cl₆H₄, but as the melting-point of this substance is so high, and considering that only a small proportion of it was obtained, I am inclined to regard it as derived from some foreign hydrocarbon contained in the anthracen employed. According to Fritzsche, anthracen melts at 210° to 212°, while dichloro-anthracen melts at 205°, and the melting-point of tetrachloranthracen is given as 220° by Graebe and Liebermann. Under these circumstances it would be surprising to find hexachloranthracen remaining unmelted at 330°. It is by no means improbable that the portion of the products which dissolves in hot benzene contains hexachloro-anthracen. This point I hope to elucidate shortly; and it is probable that, by employing a mixture of antimony chloride with some inert solvent, such as carbon tetrachloride, the violence of the action—especially that which takes place when the antimony first combines with chlorine—may be obviated, and that the carbonisation of the product may be considerably lessened.

Action of Iodine on Anthracen.

When anthracen is fused with excess of iodine, hydriodic acid is evolved, and on heating the mixture to its boiling-point the amount of hydriodic acid set free becomes considerable. If the mixture is now digested as long as hydriodic acid is evolved, and is then neutralised with soda, it will be found that the hydrocarbon has become transformed into a carbonised mass weighing rather more than the original anthracen. This charred mass, when heated in a tube, yields a small quantity of a sublimate consisting principally of free iodine, and it yields only a small portion of soluble matter to hot acetic acid or benzene. From this it is evident that the greater part of the anthracen is carbonised by long boiling with iodine.

In order to prevent the carbonisation of the greater part of the anthracen, 1 part of this hydrocarbon was carefully fused at 155° with 20 parts of iodine. As soon as the substances began to melt hydriodic acid was evolved, and when the fusion was complete and the materials were well mixed, the whole was cooled, powdered, and treated with soda solution. After the black residue had been washed and dried, it was extracted with boiling benzene, and it was found to yield a larger proportion of soluble matter than that obtained in the previous case, but the proportion not carbonised was still small.

When a solution of iodine in phenol (about 1 part to 6) is heated to its boiling-point no hydriodic acid is evolved, but if anthracen be added to the mixture, and heat be again applied, hydriodic acid is given off.

The facility with which iodine acts on anthracen is remarkable, and there can be but little doubt that the first step of the reaction consists in the formation of addition-compounds or substitution-compounds which are afterwards decomposed. Towards the solution of this point I am now directing my attention, and I hope, either by modifying the action of the iodine by means of a solvent, or by the action of iodine in conjunction with an oxidising agent, to obtain some definite results.

September 13, 1873.

NOTES AND QUERIES.

Black-Lead.—I should feel much obliged if you would kindly inform me, through the columns of your valuable paper, of the process the plumbago has to undergo to make it into cakes of "black-lead" for polishing stoves as sold by Nixey and others.—A COUNTRY SUBSCRIBER.

German Yeast.—I find the best Dutch distillers compose their grist in the proportion of 3 bushels of malt meal to 10 of rye meal; after fermentation, a considerable quantity of the meals and yeast will have settled to the bottom of the gyle tuns. Do the Germans, in making up their yeast for this country, add the settlings to the top yeast?—AROMA.

Action of Pyrogallate of Potash on Nitrous Oxide.—Having seen it generally stated that pyrogallate of potash had the power of absorbing free oxygen, and thus indicating the difference between mixtures and chemical compounds, it occurred to me to try its action on pure dry nitrous oxide. A cylinder of the gas was collected over mercury, and two glass bulbs of about 1 c.c. capacity introduced into the gas. One of the bulbs contained pyrogallate of potash in solution, the other caustic potash. The cylinder was then closed with the thumb and shaken until the bulbs were broken, and then replaced with the mouth under the mercury. A few days after, the mercury not having risen in the tube, the gas in the cylinder was tested, and, to my surprise, instantly extinguished a taper, and in general reacted like nitrogen. Had the oxygen really been absorbed by the pyrogallate, the nitrogen would, of course, have occupied the original volume, since 2 vols. N₂O contain 2 vols. N. A second cylinder, filled at the same time, and treated with pyrogallate of potash as before, was left ten days over the mercury, then transferred to water. The water soon began to rise in the cylinder, and in ten days had absorbed 9-10ths of the gas. As nitrogen is not soluble in water, and nitrous oxide does not extinguish a taper, can some of your readers inform me what gas it was?—E. J. H., New York, August 29, 1873.

KING'S COLLEGE EVENING LECTURES.

CHEMISTRY.—MR. W. N. HARTLEY.

Mondays and Thursdays, at 7 o'clock. Fee for the Course ending in March, £1 12s. 6d.

CHEMICAL ANALYSIS.—MR. W. N. HARTLEY.

Tuesdays, from 7 till 9 o'clock. Fee, £2 2s.

PRACTICAL CHEMISTRY.

Laboratory, 60, Gower Street, Bedford Square, W.C.

Mr. Henry Matthews, F.C.S., is prepared to give instruction in all branches of **PRACTICAL CHEMISTRY**, particularly in its application to **MEDICINE, AGRICULTURE, and COMMERCE.**

The Laboratory is open daily, except Saturday, from ten to five o'clock; on Saturday, from ten till one o'clock.

Mr. Matthews is also prepared to undertake **ANALYSES** of every description.

For Particulars and Prospectuses, apply to **Mr. Henry Matthews**, the Laboratory, 60, Gower Street, Bedford Square, W.C.

Analysis of Food, Water, and Air.—MR.

WANKLYN has opened a Laboratory at 117, Charlotte Street, Fitzroy Square, and is prepared to give Practical Instruction in Chemical Analysis to Medical Officers of Health, and to persons proposing to undertake the duties of Public Analysts under the new Ad.

Royal Polytechnic Institution, 309, Regent Street.—Laboratory (entirely re-fitted) and Class-Rooms are now open.

ASSAYS, ANALYSES and Investigations connected with **PATENTS** conducted.

Pupils received for Class and Private Study. Special facilities are offered to persons preparing for **GOVERNMENT EXAMINATIONS.**

Classes are now forming for Practical Study in **CHEMISTRY, STEAM, and PHYSICS.**

For particulars, apply to **Professor E. V. GARDNER, F.A.S. M.S.A.** at the Institution.

North London School of Chemistry, Pharmacy, &c.

Established 12 years.—Conducted by **Mr. J. C. BRAITHWAITE**, for thirteen years Principal Instructor in the Laboratories of the Pharmaceutical Society of Great Britain, and Demonstrator of Practical Pharmacy, Pharmaceutical Latin, &c.

The Session 1873-1874 commences on the 1st of October, when—
The **LABORATORY** will be open for instruction in Practical Chemistry as applied to Pharmacy, Medicine, Analysis, &c. Terms moderate.

The **CLASSES** for **CHEMISTRY, MATERIA MEDICA, BOTANY, and LATIN**, meet as usual at 8 p.m.

Fee to either Class Half-a-Guinea per Month. Pupils desirous of doing so can attend until qualified for one inclusive Fee.

The **BOTANICAL GARDEN** affords every facility to Students desirous of acquiring a *Practical Knowledge of Botany*. During the Season **BOTANICAL EXCURSIONS** are made every Saturday at 10 a.m.

As each Pupil works independently, he can enter at any period to either Classes or Laboratory.

All Fees must be paid in advance.

PRIVATE TUITION for the Preliminary Modified Minor and Major Examinations, &c.

A few Pupils received to Board in the house.

Applications, accompanied with a stamped envelope, addressed to—

54, KENTISH TOWN ROAD, N.W.

BERNERS COLLEGE of CHEMISTRY.

EXPERIMENTAL MILITARY and NAVAL SCIENCES, under the direction of **Professor E. V. GARDNER, F.R.S., &c.** of the late Royal Polytechnic Institution and the Royal Naval College.

The Laboratory and Class Rooms are open from 11 to 5 a.m., and from 7 to 10 p.m. daily.

Special facilities for persons preparing for Government and other examinations.

Private Pupils will find every convenience.

Analyses, Assays, and Practical Investigations connected with Patents, &c., conducted.

For prospectus, &c., apply to **Prof. E. V. G., 44, Berners-street, W.**

THE LIVERPOOL COLLEGE OF CHEMISTRY, 96, DUKE STREET, LIVERPOOL.

Specially Devoted to the Study of **CHEMISTRY, TECHNOLOGY and ASSAYING.**

Laboratories open throughout the Year.

MARTIN MURPHY, F.C.S., &c., Principal (Successor to the late **Dr. SHERIDAN MURPHY**).

A Special Laboratory is devoted to Commercial Analyses of every description, and to Mineral Assays.

Manufacturers' and Smelters' Analyses and Assays undertaken on Contract.

Patentees and Inventors Advised and Assisted. Works and Mines Inspected. The Erection of Manufacturers' Plant Supervised, &c.

Terms and Fees VERY MODERATE.

Further Particulars and Full Prospectus on application to The Principal, **MARTIN MURPHY, F.C.S. &c.**

SUPPLEMENT TO THE CHEMICAL NEWS.

VOL. XXVIII. No. 722.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Under this heading will be found an encyclopaedic list of chemical papers published abroad during the past week, with abstracts of all susceptible of advantageous abridgment. The two half-yearly volumes of the CHEMICAL NEWS, with their copious indices, will, therefore, be equivalent to an English edition of the "Jahresberichte."

NOTE. All degrees of temperature are Centigrade, unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances de l'Académie des Sciences, August 25, 1873.

M. Zöllner's Theory of Solar Scorizæ.—M. Faye.—This theory is, briefly, as follows:—The spots are scorizæ produced by local cooling of the incandescent liquid which forms the solar globe. Their relatively low temperature gives rise to currents analogous to those about our coasts and islands; only in the sun they do not alternate. The lower currents flow perpendicularly to the sides of the islet from within outwards; the upper from without inwards. Hence a continual series of vertical movements, the horizontal axes of which are *tangential* to the contours of the scorizæ. Naturally the solar radiation is partly suppressed by such an islet; and if the temperature sinks to the point of condensation of vapours in the atmosphere clouds are formed, whose figure depends on the upper currents flowing from all parts towards the vertical axis of the islet. They will especially be produced towards the central part, and the scoria will appear as a dark nucleus with its *enceinte* of penumbra. This local cooling, and the descending movement of the atmosphere towards the interior, will explain the depression observed at the dark nucleus of spots, and the effects of perspective as they approach the edge of the disc. If the ascending currents outside of the islet are strong they will leap up and give the appearance of ordinary protuberances. As to the eruptive protuberances, they are due to a local diminution of atmospheric pressure. The gases included and compressed, or simply dissolved in the liquid mass, escape like the gas-bubbles in seltzer water when the cork is drawn. The movements of spots are explained by "trade-winds" from the poles to the equator. The component of this action in the direction of the parallels diminishes the velocity of rotation, and retards the spots more in regions near the pole than at the equator, where the action is *nil*. Large scorizæ often break up and form several spots, the incandescent ocean appearing from below. Remarking on this theory M. Faye points out that the spots on nearing the edge ought, according to it, to show a projection at the side of the sort of vase of which the scorizæ forms the bottom: but there is nought of this, and the orifice becomes even with the edge of the disc. The depth of the spots has been measured, and found on an average three to four seconds. Everything indicates that the spots are cavities and not projections. On the other hand, the theory is more closely related to his (M. Faye's) own than P. Secchi's; both supposing a circulation and *down rush* of hydrogen; the axis, however, being according to the author vertical. And it is also preferable to the eruption theory in that it agrees with laws of movement of the spots, one of these being that

each spot follows the movement of the parallel in which it is, and if it passes into another parallel takes the movement of that. But then one would suppose that the islets of scorizæ would be driven by the trade-winds supposed, towards the equator (like our ships). There is no such movement, and one even finds neighbouring spots which have limited movements in opposite directions, one towards the equator, the other towards the poles. The elliptical oscillation, too, has nothing in common with the displacement of floating bodies, and the phenomena of segmentation are hardly explained. The scorizæ (if such there were) would doubtless be formed in the hottest regions; but, on the contrary, they appear in the zones nearest the equator, never at the poles. The spots do not appear beyond the 35th degree of latitude, while the protuberances (supposed to be produced by them) appear as far as the 70th. Lastly, consider the long and constant solar radiation. The sun being simply a liquefied mass would have been long since encrusted. If the conductivity of liquids and solids is so small that these scorizæ resist the heat of the liquids for days, weeks, and even whole months, how are we to explain the enormous radiation of 1,200,000,000 calories per square metre of surface daily? A state of fluidity nearly gaseous is necessary to allow the play of ascending and descending currents to bring heat up from the depths of the solar mass and supply the superficial radiation during millions of years, and to allow of the progressive contraction of the greater portion of the mass repairing, in calories, a part of the secular loss. M. Faye considers that the circulation of solar hydrogen arises from a more general phenomenon than that supposed by M. Zöllner, viz., the vortical movements (with vertical axes) produced in the photosphere by its own special mode of rotation; and then radiation is connected with a still more general phenomenon, the mode of alimentation of the photosphere.

Thoracic and Abdominal Phosphorescent Organs of Cocuyo de Cuba (*Pyrophorus noctilucus*, *Elater noctilucus* L.).—MM. Robin and Laboulène.—The authors state that the light first appears in the centre, then spreads throughout. A yellow linear zone of adipose tissue at the exterior, at length becoming luminous, is yet not photogenic; it only reflects the light produced by the central part. But it does so, not only from its internal face but throughout its thickness, the action being favoured by the transparency and high refringent power of the fatty globules. The phenomena of dispersion and interference thus produced are the cause of the remarkable brilliancy appearing when the light from the centre reaches as far as this zone. As to the changes of molecular state in the tissue proper of the organ, the authors think the phosphorescent tissue produces a substance which slowly accumulates in the cells independently of all nervous influence, and of the same order with other secretions; and that only the act by which it is discharged is voluntary. The principle rendering the cells luminous behaved like the *noctilucae* extracted by Phipson. The abundance of urates in the cells makes it probable that uric acid results from the photospheric decomposition of the preceding coagulable compound. The large number of tracheæ in the apparatus is doubtless connected with the consumption of oxygen accompanying the phenomena.

Direct Demonstration of the Fundamental Principles of Thermo-Dynamics.—Continued extract from memoir by M. Ledieu.—This gives a direct demonstration of the amplified principle of Carnot.

Rapidity of Production of Phylloxera.—M. Lichtenstein.—The author considers that nine generations often appear in the three summer months. (A letter from M. Dumas describes the good effects of sulphide of carbon as a remedy against the insect.)

Spectrum of the Comet III. of 1873.—MM. Wolf and Rayet.—It consists of a continuous spectrum from the yellow to the violet, due partly to reflected solar light, and of two luminous bands, one in the green the other in the

blue, both diffuse towards violet. It is thought the comet may have a solid nucleus.

Spectrum of the Solar Atmosphere.—M. Rayet.—In studying a large faculae on the 16th August the author observed a peculiar mode of reversal of the line D. At a certain height *one only of the two lines*, the less refrangible, appeared luminous; and nearer the edge, when both lines were reversed, the less refrangible was always brighter than the other. The eruption at this point retained this character some time, for on the 24th the singular reversal was again observed. The author thinks it a general law that in a group of neighbouring lines of a substance it is the less refrangible that is most readily reversed.

Influence of Changes in Barometric Pressure on the Phenomena of Life.—Twelfth note by M. Bert.—When oxygen accumulates to about 30 per cent in the arterial blood (of a dog) it produces convulsions; and the fall of temperature which occurs indicates a profound change in internal nutrition. It is not that the blood becomes a poisonous substance through superoxidation, but that the excess of oxygen in the tissues themselves alters the chemical phenomena of nutrition. Similarly compressed oxygen hinders the germination of seeds, the putrefaction of fragments of muscle, the change of starch into sugar by saliva, the development of *Mycoderma aceti*, and a number of like phenomena.

Of Hay Asthma, or Hay Fever, as a Morbid Entity.—M. Decaisne.—He thinks the emanations from forage plants only play a very secondary part in the disorder, which attacks people whether exposed to these or not. It occurs in any season, and annual periodicity is not proved. It is "a catarrhal fever, influenced and modified in its various causes, in its progress, and, according to individual aptitude, by atmospheric conditions which produce acute affections of the bronchi."

On a Principle of Union of Universal Chemistry applicable to Organic Chemistry.—M. E. Martin.—The chemistry which we call universal comprehends the two electricities as material simple bodies, and establishes their properties, physical and chemical. It is founded, moreover, on the knowledge of the true ponderable elements, those which are at present recognised as such being mixed compounds; that is to say, being formed by a primary union, in definite proportions, of the true elements with the two simple imponderable bodies. According to universal chemistry, the elements, ponderable and imponderable, are divided into two classes according to their affinities. Those which possess the affinity of oxygen form the oxy class, comprising oxygen—which is *not* oxygen gas,—fluor, chlorine, bromine, iodine, and nitrogen, and by the simple imponderable body *electricité* (symbol, El), which is the so-called negative electricity. The basic class is formed by the elementary bodies, hydrogen—of which hydrogen gas is a compound,—carbon, sulphur, phosphorus, selenium, arsenic, boron, silicon, all the metals, and the imponderable body *etherile* (Et), known as positive electricity. Bodies of the same class cannot unite directly with each other. There are four modes of chemical union, one of which only has been known hitherto:—1. Union of the two simple imponderable bodies among themselves, which yields as product light and heat. 2. Union of simple ponderable bodies of the basic class to the simple imponderable body of the oxy class, which gives combustible compounds, such as hydrogen gas, &c., and that of the simple ponderables of the oxy class to the imponderable of the basic, which yields oxygen and chlorine gases, &c. 3. Union of the compound bodies among themselves, which may take place in two distinct manners, without alteration in the constitution of the bodies which unite. In this manner unstable compounds are formed, as takes place in organic bodies. 4. Union between combustible and burning (*comburants*) bodies with double decomposition. The last-mentioned mode, in its two forms, the dry and the humid, is the only one hitherto known. (The substance

of this memoir was put forward by the author several years ago in a work entitled "Nouvelle Ecole Electro-Chimique").

Les Mondes, Revue Hebdomadaire des Sciences, par L'Abbé Moigno, Tome xxxii., No. 1, September 4, 1873.

This number contains no original chemical matter.

No. 2, September 11, 1873.

Horsky's Diffusion Apparatus.—This apparatus does away with the rasping process in the manufacture of beet-root sugar, dispenses with three-fourths of the manual labour, and extracts the saccharine matter completely. The yield of sugar obtained by the use of this arrangement has this season amounted to 8.5 per cent, an amount greatly superior to that obtained in neighbouring establishments where other processes for extraction are in use.

Dr. Jeannel's Horticultural Manure.—

Nitrate of ammonia	400 parts.
Biphosphate of ammonia ..	300 "
Nitrate of potash	250 "
Hydrochlorate of ammonia ..	50 "
Sulphate of lime	60 "
Sulphate of iron	40 "

Eudiometric Pipette.—M. Jean.—A modification of Regnault's apparatus, which would not be intelligible without the accompanying illustration.

Gases of Petroleum and of Resin.—M. Benavites.—A comparison of the illuminating power of these gases with common coal-gas.

Solidification of Nitrous Oxide.—M. T. Will.—The solidification of this body is readily obtained by passing a rapid current of air across the liquefied gas. Unlike liquefied carbonic acid the protoxide of nitrogen can be kept for a long time in a liquid state in open vessels. The protoxide of nitrogen when liquefied boils at -92° , and solidifies at -99° , so that the tension of its vapour is less than 1 atmosphere. The specific gravity of the liquid protoxide at 0° is 0.9004; its coefficient of dilatation is considerable, and it is insoluble in water.

New Series of Aromatic Hydrocarbides.—Th. Zincke.—By the reaction of powdered zinc upon a mixture of benzol and chloride of benzyl the author obtains, besides diphenyl-methan, two isomeric dibenzyl-benzines, $C_{20}H_{18}$.

New Method of Preparing Caustic Soda.—M. Helbig.—The crude lye is evaporated in cast-iron boilers. At a certain heat the cyanides contained in the pasty mass are decomposed with escape of ammonia, and deposition of carbon. When this point is reached the heat is raised to redness, and the mass becomes more fluid. A sheet-iron cover is then fitted upon the boiler, provided with an opening through which enters an iron pipe. The graphite is plunged into the mass and air is forced in. The graphite which separates rises to the surface and may be collected. The mass is tested from time to time to see if the sulphur is perfectly oxidised. When this is the case the blast is stopped, the mass allowed to become clear, and run off as usual.

Examination of Grape Sugar and Milk Sugar.—M. Campani.—The author employs as reagent a concentrated solution of subnitrate of lead, mixed with a dilute solution of acetate of copper. The liquid to be tested is added to 5 c.c. of this solution and raised to a boil. If grape-sugar is present the mixture becomes coloured, and gives a yellow precipitate. Cane-sugar has no action. A dilute solution of milk-sugar behaves like grape-sugar. If the solutions of these sugars are concentrated the precipitates are brick-red.

Action of Soap Lyes on Incandescent Metals.—M. Barette.—The author finds that balls of red-hot metal are scarcely cooled by immersion in soap solutions. It appears as if the presence of soap in the water facilitated the assumption of the spheroidal state. Albumen, glyceria, and other organic matters have a similar action.

Bulletin de la Société Française de Photographie,
No. 8, 1873.

At a general meeting of the Society, August 1, 1873, a letter from M. Anthony, of New York, offering the following prizes, open to photographers of all nations:—100 dols. for the best bust of a lady; 100 dols. for the best head of a boy under six years of age; 100 dols. for the best head of a girl under six years of age; 100 dols. for the best group of two children under six years of age; 100 dols. for the best landscape. The proofs to be 16½ by 21½ centimetres, mounted on cards 2½ by 3½ centimetres.

M. Guilleminot presented to the Society a photographic trough made of hardened gutta-percha. This material resists elevated temperatures better than the ordinary gutta-percha.

M. Davanne gave an account of the photographic department of the Vienna Exhibition.

M. Champion gave the following as the result of his experiments on the preparation of gun-cotton:—The acid mixture consists of 2 measures of nitric acid at 40° B. (?), obtained by mixing common and fuming nitric acids. 3 measures of sulphuric acid at 66°. The mixture may be used either cold or at 40° C. The cotton is left in contact with the acid for three minutes, and the product washed till perfectly neutral.

M. H. Pellet gave an experimental demonstration of the process of M. J. Chrselshom for freezing silver baths from an excess of iodide of silver. He takes a common solution of nitrate of silver, to which are added a few c.c. of a solution of iodine in water slightly alcoholised. The liquid becomes yellow and turbid without precipitation. 2 or 3 drops of pure hydrochloric acid are then added. A precipitate of chloride of silver falls. The liquid is stirred, and on standing the supernatant solution contains the greatest part of the iodine added. The chloride of silver recently precipitated is decomposed by the iodine. Iodide of silver is formed and thrown down along with the excess of chloride of silver.

Sensibility of Different Layers of Collodion.—M. Redon.—The author finds that opaque films of collodion receive an impression rapidly, and show an intense colouration, whilst transparent glassy films are impressed more slowly and feebly, and sometimes not at all.

Polychromic Photography.—Leon Vidal.—A repetition and expansion of the process briefly described in the last number, with an account of certain specimens of photographs in colours.

Revue Scientifique de la France et de l'Etranger,
September 6, 1873.

This number is taken up with an account of the Lyon meeting of the French Association for the Advancement of the Sciences. At one of the "Public Conferences" M. A. Gaudry delivered a lecture on the modern progress of chemical industry. He informed his audience that the amount of sulphuric acid manufactured annually in Europe amounts to 800,000,000 kilos, and would fill a canal 2 metres deep, 10 wide, and 25 to 30 kilometres in length. To yield this acid 800,000 tons of pyrites are yearly consumed. The condensation of the hydrochloric acid liberated in alkali works; the improvements of Mr. Weldon and Mr. Deacon in the manufacture of chlorine; the revolving soda-furnace; the extraction of potash as a secondary product in the manufacture of beet-root sugar; and the recent improvements in producing paper-pulp from wood, are among the principal points touched on in the remainder of this popular and able lecture.

Revue Hebdomadaire de Chimie Scientifique et Industrielle
par Ch. Mène, June 12, 1873.

This number contains no chemical matter.

Reimann's Färber Zeitung, No. 29, 1873.

This number contains a notice of the tinctorial department of the Vienna Exhibition.

There are receipts for dyeing a dark grey on wool; a silver grey, an olive, and a bright olive on the same material.

For a scarlet on wool, woollen yarn, and woollen cloth, capable of bearing the milling process, the author gives the following formula:—To 10 lbs. of material take 1½ lbs. of oxalic acid, 7½ ozs. tin crystals, 3 ozs. flavin, and 1½ lb. cochineal.

There are also receipts for a lac scarlet, and a grain orange on wool; a catechu black on silk; a finish for cottons; a logwood blue for cotton-wool; a yellow on the same fibre; and an anilin green on cotton, which we quote.—For 10 lbs., allow the goods to soak three hours in a hot solution of ¼ lb. tannin. The cotton thus mordanted is dyed in a recent cold solution of either iodine or methyl green acidulated with acetic acid; picric acid being added if a yellower tone is required.

There are also directions for a cheap logwood blue on cottons, and a reseda on old white silks produced by means of quercitron after mordanting with nitrate of iron.

There is a notice of Lamy's patent for brown on cotton by printing upon the goods nitrate, acetate, or hydrochlorate of naphthylamin with chlorate of potash, a salt of copper, or hydrofluosilicic acid. The calico is then exposed to the air, and passed first through an acidulated bath of chromate of potash, and finally through an alkaline solution. The brown is equal in permanence to an anilin black.

Dufréné proposes to pass tissues which are liable to be exposed to wet through a dilute solution of tannin, and then through chromate of potash till they turn brown, when they are washed and dried.

For an antichlore, sulphite of soda is recommended as preferable to the hyposulphite, which generally leaves a yellowish deposit of sulphur in the fibre.

In Lauth's process for fixing anilin green on wool by working in a bath of hyposulphite acidified with hydrochloric acid, an addition of alum is recommended to restore the elasticity of the wool, and free it from a smeary handle. The following two receipts for soap are given by a manufacturer of silicate of soda. For a toilet soap take 150 lbs. cocoa-nut oil; 50 lbs. lye at 40 per cent; 50 lbs. silicate of soda; and 5 lbs. of glycerin. For a fuller's soap take of fat 100 lbs.; potash lye at 30 per cent, 10 lbs.; potato starch, 10 lbs. in 20 lbs. of water; and 10 to 12 lbs. of silicate of soda at 30 per cent. Here there are 88 lbs. of adulterants to 100 lbs. of fat. Such soaps cannot be distinguished from genuine kinds by mere inspection. In order to dye an anilin black on yarn it is recommended to precipitate peroxide of manganese on the fibre, and then treat with anilin black.

No. 30, 1873.

This number contains receipts for a reddish drab grey on wool and woollen yarns; for a darker shade on the same materials; a reddish mode drab; a red-brown on wool and yarns; a blackish violet, a dark dahlia, a mulberry and an olive-brown on woollen piece-goods; a bright green capable of bearing milling on woollen yarn; for printing a fast steam black on wool; for a bright and fast green on cotton; a fine and cheap reddish brown on woollen yarn; for dyeing stiffened cotton yarns; and for black on linen yarn.

Rave proposes to treat dye-woods with soda or lime, and precipitates the solution with hydrochloric acid. The precipitated colour is sold as paste or powder.

Leather can be tanned in six days with a mixture of 10 parts tobacco root, 60 parts catechu, and 30 parts sumac.

The following receipt has been patented for scarlets on cotton:—2 lbs. solution of lac, 1½ lbs. of gum, 1 lb. tin crystals, 1 lb. oxalic acid, 8 quarts of water, and 1 quart decoction of oak-bark.

No. 31, 1873.

This number contains a list of the manufacturers of tinctorial chemicals to whom prizes have been awarded at

the Vienna Exhibition. We find no English name in the catalogue.

There are receipts for dyeing wool a bright green; for a finish for pack-thread; for a reseda on genappe; a brown on silk; a printing black on cotton yarn; a blue-black on old cotton, velvets, and velveteens; a chamois and rose on old goods with cotton warps, saffranin on a sumach mordant being recommended for the latter; a black on mixed woollens and silk; a dark green on wool; a cheap violet on woollen piece-goods. For this the author recommends per 100 lbs. of cloth to boil for an hour-and-a-half with $2\frac{1}{2}$ lbs. chromate of potash, $1\frac{1}{2}$ lbs. blue vitriol, $\frac{1}{2}$ lb. oxalic acid, and $\frac{1}{2}$ lb. sulphuric acid. The cloth is either allowed to cool in the decoction, or rinsed at once, and dyed in a fresh bath with 40 lbs. of logwood, 10 lbs. camwood, and $2\frac{1}{2}$ lbs. of orchil, boiling for one hour. There are also receipts for a chestnut and a scarlet on wool, and for printing a black on flamed woollens. The editor extracts from a contemporary the following formula for a yellow:—"To an armful of woollen yarn take three table-spoonfuls of tin crystals, a saucer-full of flavin, and a milkpot full of oxalic acid. The whole is allowed to boil up, and so much water added that the operator can bear his tongue in the bath. The yarn is then entered, the heat raised to a boil, and the goods worked while the Lord's Prayer can be repeated twenty times!" Dr. Reimann, very pardonably, adds a sarcastic comment on such a gem of technological literature.

For bleaching wool the bisulphite of soda is proposed dissolved in water, and mixed with two-fifths its weight of hydrochloric acid.

Mahogany and rosewood yield a colouring matter resembling catechu. The rasped woods are roasted like starch, then extracted with water, and the liquid evaporated to the consistence of a syrup, or to dryness.

MISCELLANEOUS.

British Association for the Advancement of Science.—The following is a list of the papers read before Section B (Chemical Science) at the Bradford meeting:—

The President's Address.

Report on the Chemical Constitution and Optical Properties of Essential Oils.

J. H. Gladstone, F.R.S.—On Black Deposits on Metals.

A. Tribe, F.C.S.—On a Specific Gravity Bottle for Inflammable Liquids.

W. H. Pike.—On the Homologues of Oxaluric Acid.

C. R. A. Wright, D.Sc., F.C.S.—On Derivatives of Codeine and Morphine.

Professor Williamson, F.R.S.—Report of the Committee for Superintending the Monthly Reports of the Progress of Chemistry.

Professor G. C. Foster, F.R.S.—Report on Siemens's Pyrometer.

W. Chandler Roberts, F.C.S.—Report on the Method of Making Gold Assays, and of Stating the Results thereof.

J. Dewar, F.R.S.E.—Report on High Temperatures.

A. Vernon Harcourt, F.R.S., and F. W. Fison, F.C.S.—On a Continuous Process for Purifying Coal-Gas, and Obtaining Sulphur and Ammonium Sulphate.

C. Y. Woodward, B.Sc.—A New Form of Gas Generator.

J. Spiller, F.C.S.—An Artificial Magnetite.

Dr. Paul and A. D. Cowley, F.C.S.—On the Valuation of Commercial Crude Anthracene.

J. Norman Lockyer, F.R.S.—Note on the Elements in the Sun.

R. B. Grantham, C.E.—Report of the Committee on Sewage.

W. T. McGowen.—On the Sewage of Manufacturing Towns.

W. Chandler Roberts, F.C.S.—On Horn Silver.

Dr. A. Schafarik.—On the Constitution of some Silicates.

Professor Crum-Brown, F.R.S.E.—On the Action of Sulphide of Methyl on Bromacetic Acid.

Charles Horner.—On the Spectra of certain Boric and Phosphoric Acid Blowpipe Beads.

Alfred H. Allen, F.C.S.—On the Detection of the Adulteration of Tea.

Alfred H. Allen, F.C.S.—On the Action of Sulphuric Acid on Ethylanilin and Dimethylanilin.

Alfred H. Allen, F.C.S.—Note on Cresol Derivatives.

Dr. H. E. Armstrong.—On Alpha- and Beta-Naphthyl Sulphide.

Place of Meeting for Next Year.—The meeting next year will be held at Belfast, commencing on August 19. President Elect—Professor Tyndall, D.C.L., F.R.S., &c.

PATENTS.

ABRIDGMENTS OF PROVISIONAL AND COMPLETE SPECIFICATIONS.

Improvements in the utilisation of the waste heat from coke ovens for the manufacture of soda ash, caustic soda, and for other similar purposes. Hugh Williams, Wigan, Lancashire. January 23, 1873.—No. 268. My invention consists principally in arranging two or more coke ovens side by side, in such a manner that their flues unite in one chamber, and charging and working such coke ovens alternately or in succession, and in employing the heat and gases evolved therefrom in a secondary furnace adjoining the said coke ovens for the manufacture of soda ash, caustic soda, and other similar manufacturing purposes.

Improvements in the purification of coal-gas, and in the production of alkaline sulphides to be employed for such purpose. Robert Hogarth Patterson, Hammersmith, Middlesex. January 23, 1873.—No. 274. This invention relates, firstly, to the production of alkaline sulphides (to be subsequently employed in the purification of coal-gas, either in the manner described in my Patent, dated March 9, 1872, No. 730, or otherwise), by decarbonating impure coal-gas—that is, gas containing carbonic acid and sulphuretted hydrogen—in alkaline washers or scrubbers or in lime-purifiers in such manner that, while the carbonic acid is arrested in the said washers, scrubbers, or purifiers, sulphuretted hydrogen is driven forward, and converts alkaline substances, such as potash or ammonia, ammoniacal liquor, or gas liquor, contained in subsequent vessels, into sulphides. I also employ the said process for the purpose of more highly sulphuretting gas liquor, whether decarbonated or not, so as to render the said liquor an efficient material for purifying coal-gas from sulphur contained therein in other forms than that of sulphuretted hydrogen. This invention relates, secondly, to a system of purification whereby the elimination of carbonic acid from coal-gas is effected by means of lime and alkalies before the said gas is passed through vessels containing alkaline sulphides, either in a solid or in a fluid form, with a view to purify the gas from sulphur contained therein in other forms than sulphuretted hydrogen.

Improvements of soup-farina. Edward Heinson Huch, merchant, Brunswick, Germany. January 24, 1873.—No. 288. This provisional specification describes dissolving extract of meat in salt water, and adding flour of various kinds.

An improved mode of or process for obtaining fertilising substance. Major-General Henry Young Darracott Scott, C.B., Ealing, Middlesex. January 25, 1873.—No. 296. The object of this invention is the manufacture of precipitated phosphates by the addition to clarified sewage water of impure phosphatic substances, such as coprolites, dissolved in acid.

Improvements in the torrefaction of animal substances for the purpose of manufacturing manure therefrom, and in the apparatus or means employed therein. John Henry Johnson, 47, Lincoln's Inn Fields, Middlesex. (A communication from the firm of Coignet, Son, and Co., Paris). January 25, 1873.—No. 305. This invention consists in torrefying animal solid and liquid substances by the direct contact therewith in closed chambers of gases superheated to a temperature of about 550° F. Also in first drying the substances by the direct contact of gases heated to about 330° F., and then torrefying as above described. Also in cooling the torrefying mass by the application thereto of jets of water or saline solutions.

A new and improved artificial stone or cement to be used in aquatic or other buildings, also moulded and made applicable to ornamental, architectural, and other purposes. Henry Adrien Bonneville, patent agent, 6, Piccadilly, Middlesex. (A communication from Messrs. Schenck, Baronet, and Hayek, acting as administrators of the company known as Weiss Cement Actien Gesellschaft, two persons resident at Vienna, Austria). January 27, 1873.—No. 310. This invention relates to the manufacturing of a water mortar, and consists in using the dolomites or magnesian stones or the minerals which contain at least 25 per cent of $MgCO_3$, or the productions of chemical fabrication, which are combinations of magnesia, and which can be reduced by heat.

Improved processes and furnace with appliances for the economical production of baryta. Thomas James Smith, of the firm of Robertson, Brooman, and Co., patent agents, 166, Fleet Street, London. (A communication from Cyprien Marie Tessié du Motay, chemist, Paris). January 28, 1873.—No. 328. This refers to an arrangement of furnace with the employment of solid or gaseous combustibles for the transformation by the dry method of sulphate of baryta into sulphure of barium and of carbonate of baryta into baryta.

THE CHEMICAL NEWS.

VOL. XXVIII. No. 723.

BRITISH ASSOCIATION FOR THE ADVANCEMENT
OF SCIENCE.

BRADFORD MEETING, 1873.

SECTION B.—CHEMICAL SCIENCE.

PRESIDENT, DR. W. J. RUSSELL, F.R.S.

"On several Homologues of Oxaluric Acid," by W. H. PIKE.—The ease with which the anhydrides of the dibasic acids enter into reaction with ammonia and the substituted ammonias, gave considerable reason to expect a similar reaction with urea. The reaction in this case might be expected to take place in one of two ways: either a body homologous with barbituric acid would be formed, as expressed in the equation—

$$\begin{array}{c} \text{H} \quad \text{CO} \quad \text{H} \quad \text{CO} \quad \text{H} \quad \text{CO} \quad \text{H} \\ \diagdown \quad \diagup \quad \diagdown \quad \diagup \quad \diagdown \quad \diagup \quad \diagdown \quad \diagup \\ \text{R} \quad \text{CO} \quad \text{O} + \text{CO} \quad \text{NH}_2 = \text{R} \quad \text{CO} \quad \text{NH} \quad \text{CO} + \text{H}_2\text{O}; \\ \diagup \quad \diagdown \quad \diagup \quad \diagdown \quad \diagup \quad \diagdown \quad \diagup \quad \diagdown \\ \text{H} \quad \text{CO} \quad \text{H} \quad \text{CO} \quad \text{H} \quad \text{CO} \quad \text{H} \end{array}$$

or a simple addition might take place, the body formed being a homologue of oxaluric acid, thus:—

As far as my experiments extend, the second equation expresses the reaction which takes place.

Succinic Anhydride with Urea.—Urea, heated with succinic anhydride in the proportion of their molecular weights to 120° to 130° C., dissolves in the fused anhydride to a thick oily liquid, which in a short time becomes solid with considerable reaction. The raw product thus obtained is powdered, and, after washing with cold alcohol to remove unaltered anhydride, re-crystallised from water. The analysis gave numbers which agree with those calculated for the formula, $\text{C}_5\text{H}_8\text{N}_2\text{O}_4$. The acid crystallises from water in small brilliant scales, which, when rapidly heated, fuse under complete decomposition at 203° to 204° C. It is nearly insoluble in cold water and alcohol; perfectly so in ether, chloroform, and bisulphide of carbon; moderately soluble in boiling water and glacial acetic acid. In concentrated sulphuric acid it is at once dissolved, and is precipitated entirely unaltered on dilution. It forms easily soluble salts with the alkalis and alkaline earth. The silver and lead salts are white crystalline precipitates, which are nearly insoluble in boiling water. The silver salt gave numbers on analysis which correspond with those calculated for the formula $\text{C}_5\text{H}_7\text{AgN}_2\text{O}_4$. The constitution of this acid will probably be—

I have therefore named it succino-carbaminic acid.

Succinic Anhydride with Sulpho-Carbamid.—Succinic anhydride enters into combination with sulpho-carbamid with the same ease as with urea. Owing to the higher fusing-point of the sulpho-carbamid, the heat must be raised somewhat higher (about 150° C.) before the mixture is completely fused; it then soon becomes solid, as in the previous case. The raw product is washed with alcohol and crystallised from water. It forms a slightly yellow-coloured crystalline powder, which possesses similar properties to those of the preceding compound. It fuses at 210.5° to 211° C. It is somewhat less soluble in boiling water and acetic acid; in cold water, alcohol, and ether, absolutely insoluble. Sulphuric acid also dissolves it, without alteration, in considerable quantity. It forms

with the alkalis easily soluble salts, and with lead and silver white precipitates, which blacken if heated. The analysis gave numbers which agree with those calculated for the formula $\text{C}_5\text{H}_8\text{N}_2\text{O}_3\text{S}$. This compound will thus be succino-sulpho-carbaminic acid—

Citraconic Anhydride with Urea.—I have not as yet succeeded in obtaining any combination between citraconic anhydride and urea when these two bodies are heated to 115° C. Carbonic acid is given off, and citraconamid is formed, most probably as expressed by the following equation:—

Citraconic Anhydride with Sulpho-Carbamid.—Citraconic anhydride, however, combines at once with sulpho-carbamid to form a body which may be named citracon-sulpho-carbaminic acid. It may be purified in the same way as the preceding compounds, which in all its properties it closely resembles. It fuses at 222° to 223° C. under complete decomposition; it also gives easily soluble salts with the alkalis, and with nitrate of silver and of lead insoluble white precipitates which blacken on heating. The numbers obtained on analysis show that this acid possesses the formula $\text{C}_6\text{H}_8\text{N}_2\text{O}_3\text{S}$, the probable constitution being—

Lactid with Urea and with Sulpho-carbamid.—Neither with urea nor with sulpho-carbamid could I obtain from lactid any combination analogous to the preceding. Lactid, when heated with urea, gave off carbonic acid and formed a substance the examination of which is not complete; with sulpho-carbamid the same body was formed, with separation of oxysulphide of carbon.

I also heated succinic anhydride with sulpho-carbanilide, but this body decomposes, under the influence of the anhydride, into phenyl-mustard oil and anilin, which then acts on the anhydride.

I propose to continue the study of the action of the anhydrides of other dibasic acids on urea and on sulpho-carbamid.

"Report of the Committee on Siemens's Pyrometer."—The following is the substance of the report presented to Section B, by Professor G. C. FOSTER, F.R.S.:—Siemens's Pyrometer is an instrument for the measurement of high temperatures depending upon the change produced by heat in the resistance opposed by platinum to the passage of an electric current. It consists essentially of a coil of platinum wire, suitably protected, and so arranged that its resistance can be measured while it is exposed to the temperature it is desired to ascertain. The importance of possessing some trustworthy method of measuring temperatures beyond the range of the air-thermometer induced the British Association to appoint a committee to examine and report upon the merits of this instrument.

The first step was evidently to test the electrical permanence of the pyrometer, and the attention of the committee has as yet been confined to the examination of this point. At the Brighton Meeting in 1872, it was reported by them that a pyrometer whose resistance was, to begin with, 9.917 B. A. units at 10° C., had a resistance of 10.502 at the same temperature, after having been repeatedly heated to redness. This change was found by Professor Williamson to be, in all probability, due to chemical alteration of the platinum caused by the combined action of the silica of the porcelain core on which the wire was coiled and of the reducing atmosphere existing inside the protecting wrought-iron tube. The committee have, since then, been supplied by Mr.

Siemens with two new pyrometers, in which, with the hope of preventing the alteration previously found, a platinum tube has been introduced, surrounding the coil and separating it from the outer iron case. This addition, however, does not seem to have caused any considerable improvement, the resistance of one of the pyrometers having been at first 9.920 at 10° , and, after being twice heated to redness, 10.462 at the same temperature; the other had, to begin with, the resistance 9.988 at 10° , and after one heating its resistance was 10.465 at the same temperature. It is, however, quite possible that little or no further change would be found to occur after the first few heatings, but the committee have been unable during the past year to make sufficiently numerous experiments to enable them to form an opinion on this point. They therefore ask to be re-appointed, and for a renewal of the unexpended grant of £30, which was originally placed at their disposal.

"Report on the Method of Making Gold Assays, and of stating the results thereof," by W. CHANDLER ROBERTS, F.C.S.—The attention of the Committee was first directed to a series of experiments which were instituted with a view to ascertain to what extent the weight of pieces of pure gold and of alloys, synthetically prepared, would be affected by submitting them to the process of assaying, and consequently how far the results of assay operations are trustworthy. These results showed that the maximum error was only 1-100th per cent of the original weight of the assay piece, and consequently that the result obtained by assaying gold represents the composition of the portion of metal under examination to the 1-10,000th part, a fact which will doubtless appear remarkable to all who are accustomed to the ordinary methods of quantitative analysis.

The committee are not unmindful that, although it is possible to attain this high degree of accuracy, it is nevertheless well known that a comparison of the assay reports of the different assayers as to the composition of the same ingot might often disclose discrepancies of 5-10,000th parts.

Thus portions of metal from nineteen gold ingots were assayed by the Mint Assayer and were then sent to five assayers, each of whom furnished an independent report. Two assayers alone agreed as to the value in each of 15 ingots, in 3 ingots three assayers were in accordance, while in one instance all the assay reports differed; and, viewing the reports generally, the discrepancies varied from 4-10,000 parts to 1 part of fine gold in 1000 of the alloy, or an average deviation of 6-10,000th parts.

These small variations assume serious proportions when they affect the value of large quantities of bullion; for instance, the value of gold coined in the Mint during the past year was £15,200,000, and a persistent error in the assay reports of only 1-10,000th part would have been attended with a gain or loss to the department of no less than £1500. The Committee have entered upon the following investigations, in the hope of being able to define the condition under which errors arise:—

The method of gold assaying, as practised in the Mint, is given in the Appendix, and the method has been deliberately adopted by all assayers with slight variations of manipulation, which have not as yet been minutely examined, as the Committee considered that when widely divergent results are obtained, the gold employed by one or other of the assayers is impure, and that either the amount of impurity has not been ascertained with accuracy, or that it altogether escapes detection. It follows, therefore, that the weight of the "cornets," when compared with the initial weight, the portion of metal operated upon appears to indicate the presence of an amount of gold which is in excess of the true amount of precious metal present in the alloy.

The Committee obtained specimens of gold from different sources, and tested them side by side with gold prepared in accordance with the directions of the Lords Commissioners of Her Majesty's Treasury, by the Chemist of the Mint for use as a standard trial plate in testing the

coinage. Great care was taken in the preparation of this gold, 80 ounces of which were precipitated from no less than 100 gallons of chloride of gold, and experiments have already shown that it is very pure. The Committee propose that they adopt it as the basis for a new series of comparisons.

"High Temperatures."—Mr. J. DEWAR, F.R.S.E., stated the substance of a report on high temperatures. It had been thought that, as a low red heat brought out only the red end of the spectrum, and the spectrum gradually extended towards the violet end as the temperature rose, this fact might be used as a means of measuring temperatures. The difficulty, however, in employing this method was that for a great portion of its length the growth of the spectrum was very rapid. There also appeared at the beginning of the spectrum a grey light, which prevented the red ray from being seen. Then the human eye was much more sensitive to some parts of the spectrum than to others. This difference between the length of the spectrum and the range of human vision would cause a mis-estimation of temperature unless the spectrum could be registered by some photographic process. He (the speaker) had, therefore, thought it better to reconsider the object of the grant made by the Association, and report rather upon the increase in the quantity of light than in the length of the spectrum. The relation between the intensity of the light evolved and the heat indicated had been already well established, though their relative rate of increase had not been ascertained. Becquerel concluded that the intensity of the light was, in mathematical language, a function of the heat, growing with very great rapidity in proportion to the latter. He came to this conclusion because the radiation of heat increases with the temperature by the same law. The experiments made by himself had led him to the conclusion that at temperatures of upwards of 1000 degrees the function was a parabolic, that is, that the temperature increases as the square of the light. He said above 1000 degrees, because that temperature was required to eliminate the effects arising from the growth in the length of the spectrum. This parabolic function gave a much slower increase of light than was estimated, by Becquerel. Experiments on radiant heat had also been conducted by him (the speaker) with a view to measuring high temperatures by a method similar to that which we employed to measure the radiation of the sun itself. A portion of the surface of the heated body whose temperature was to be ascertained was caused to radiate its heat on the blackened surface of a cube containing water, and from the number of degrees which the temperature of the water rose in a fixed time, the heat of the radiant body was concluded. Whilst on this line of experiment it was found that MM. Dulong and Petit's law did not hold good above a low red heat, the explanation probably being that the violet light waves did not carry so much energy as the larger red ones.—Mr. DEWAR, who had at considerable length and with much facility of illustration, explained the results of the report instead of reading it, concluded amidst some applause.

Dr. GLADSTONE said the chief difficulty that had occurred to him with regard to the measurement of high temperatures by the spectrum was that it would be far from easy to determine where one colour ended and another began, and this very difficulty had proved insuperable. Even the same spectrum was different in appearance to different eyes. When he was experimenting in association with the late Sir D. Brewster he noticed that the latter could see rays of much lower refrangibility than he (the speaker) could, whilst he could see a greater portion of the violet end of the spectrum than could Sir David Brewster. However, by the several methods which had that day been explained—including the Siemens pyrometer—they were placed in a position to make comparison of one with another, and thus obtain a reliable result.—A few further remarks were made (it being observed that although they had several means of comparing

high temperatures relatively to each other, there were as yet no means of ascertaining the absolute temperature registered by pyrometers), and the President closed the discussion by a hope that the committee would continue its investigations next year.

"On a Continuous Process for Purifying Coal Gas from Sulphuretted Hydrogen and Ammonia, and for Extracting Sulphur and Ammoniacal Salts," by A. VERNON HARCOURT, F.R.S., and F. W. FISON, F.C.S.—The introduction of "oxide" for purifying "foul gas" has furnished the gas-maker with a process which might fairly be described as continuous when compared with the use of lime. But after the oxide has been alternately sulphurised and revived twenty or thirty times, it is rendered inert by the accumulation of sulphur, and fresh oxide has to be substituted for it. The spent material, consisting of a mixture of oxide and sulphur in about equal bulks, is either burnt like pyrites on the hearth of the vitriol-maker, or it is heated until the sulphur is separated by sublimation. In either case the oxide itself is rendered anhydrous by the action of heat, and cannot be used again for gas purification.

Ammonia is most commonly removed from gas by "scrubbing," and the construction of scrubbers and the mode of working them has been brought to great perfection. Nevertheless this process is liable to some objections. The scrubbers are bulky erections, and the cleansing of them, which is generally found to be necessary from time to time, is a troublesome operation. Also, the ammonia is not obtained in the most portable and saleable form, as a solid salt, but as a solution containing perhaps 20 ozs. of ammonia in a gallon of water. Although the volume of water used in scrubbing gas is relatively very small, it cannot fail to produce some reduction of illuminating power, since olefiant gas is far from insoluble, and a more copious washing reduces the illuminating power in a very noticeable degree. The use of copperas, or of sulphuric acid and sawdust, or of other substances that may be employed in a similar manner, is commonly designed to supplement the use of scrubbers, and requires the appropriation of a distinct set of purifiers, or at any rate, the material used to stop ammonia must be kept separate from that which is used to stop sulphuretted hydrogen.

The extraction of sulphur from the spent oxide, and the manufacture of ammoniacal salts from the liquor, are operations which the gas manufacturer generally makes over as too troublesome for him to undertake to the manufacturing chemist. The process about to be described is one which we believe it will be both advantageous and easy for the gas manufacturer to conduct upon his works. It effects the removal of sulphuretted hydrogen and of ammonia simultaneously, and yields sulphur and sulphate of ammonia in a nearly pure state. It renders the erection of scrubbers, and pumping, and the washing of gas with water unnecessary. It restores the oxide, from which sulphur and sulphate of ammonia have been extracted, to the purifiers in the form of pure hydrated oxide, so that the same oxide may be used for an indefinite time. The new process is at once applicable wherever oxide is, or can be, used as the agent of purification, the only differences in the mode of working being that the oxide, during revivification, is moistened with a solution of ferric sulphate (persulphate of iron), and that a portion of the oxide is removed from time to time, and treated in the following manner:—It is first extracted with water, by the use of an arrangement similar to that employed in the extraction of black-ash. The soluble salts are sulphate of ammonia, formed in the purifiers by the reaction of ammonia and ferric sulphate, and, in smaller quantities, sulphocyanide, hyposulphite, and, probably, other salts of ammonia. This extract is mixed with a small excess of sulphuric acid, and yields, when concentrated by evaporation, crystals of sulphate of ammonia. The remainder of the substance is then boiled with dilute sulphuric acid, which dissolves the oxide, and

leaves a residue of sulphur. The actual process of extraction by acid consists in treating the substance successively, (1) with a solution of ferric sulphate, containing some free sulphuric acid; (2), with a more dilute solution of ferric sulphate to which sulphuric acid has been added; (3 and 4), with more dilute solutions of ferric sulphate, all these liquids being the produce of a former extraction; and (5), with water. The liquid resulting from the first of the treatments enumerated above is a strong solution of ferric sulphate, which is used, as already mentioned, by being mixed with the charge of oxide before it is replaced in the purifier. The residue, after the final washing, consists almost entirely of sulphur, and requires only to be dried. It will be evident that all the oxide which has been freed from sulphate of ammonia and sulphur by this treatment passes into the condition of ferric sulphate, and, in this condition, is replaced in the purifier. There it again becomes oxide by the action upon it of the ammonia of the gas, which it completely removes, while the ammonia is fixed as sulphate.

In order to obtain by one operation all the ammonia found in the retorts, and to ensure the passage into the purifiers of a quantity of ammonia sufficient to neutralise all the acid employed in dissolving the oxide, we propose further to run the liquor from the condensers into a chest heated by steam, through the top of which a current of gas passes, which is drawn from beyond the exhaustor, and re-enters the main leading to the condensers. By a suitable arrangement, the condensed liquor may run continuously through this chest, passing off after it has been heated in the current of purified gas.

"On the Valuation of Commercial Crude Anthracen," by Dr. PAUL and A. J. COWNLEY.—The authors proposed for the present unsatisfactory method of testing crude anthracen, that anthraquinon should be used as a basis of valuation. They had found that 178 parts of good anthracen were equivalent to 208 parts of anthraquinon. The melting-point for anthraquinon they had found to be 276°. The agent they recommended for oxidising the anthracen was a solution of chromic anhydride in glacial acetic acid. In reply to Drs. ARMSTRONG and MILLS, Dr. PAUL said it would take three days to make an estimation of anthracen, and that he could not vouch for the absolute purity of the anthracen he used as a standard.

Mr. J. NORMAN LOCKYER, F.R.S., read a paper "*On the Elements in the Sun.*" He did not come before the section as a chemist, but as an amateur interested in certain inquiries which day by day seemed to be breaking out in a curious way in a chemical direction; and in prosecuting those inquiries he sought the assistance of the chemists. He believed that the more they knew about the sun and stars, the better it would be for astronomers and physicists and chemists as well. Mr. Lockyer then explained the processes by which, with the aid of the spectrum analysis, he was able to discover the composition of the sun. Mr. Huggins and Father Secchi had both paid great attention to the subject; and from the result of their observations and his own he had come to the following conclusions:—First, the absorption of some elementary and compound gases was limited to the most refrangible part of the spectrum when the gases were rare, crept gradually into the visible violet part and finally to the red end of the spectrum as the pressure was increased. Second, the absorption of the photospheric light, and therefore the temperature of the photosphere of the sun was much greater than had been supposed. Third, the lines of compound metallic vapours lay generally in the red end of the spectrum, and this held good for absorption in the case of aqueous vapour. Such spectra, like those of the metalloids, were separated spectroscopically from those of the metallic elements by their columnar or banded structure. Fourth, there were, in all probability, no compounds ordinarily present in the sun's reversing layer. Fifth, when a metallic compound vapour was dissociated by the spark, the band spectrum died out, and the elemental lines came in according to the degree of tempera-

ture employed. Again, although their knowledge of the spectra of the stars was lamentably incomplete, he gathered the following facts from the work already accomplished with marvellous skill and industry by Secchi, of Rome:—First, the sun, so far as its spectrum went, might be arranged between stars with much simpler and with much more complex spectra. Second, Sirius, as a type of the former, was the brightest and therefore probably the hottest star in our northern sky; was only known to contain hydrogen, sodium, and magnesium; and the hydrogen lines in this star were enormously distended, showing that the chromosphere was largely composed of that element. There were many other bright stars of this class. Third, as types of the much more complex spectra, the red stars might be quoted, the spectra of which were composed of channelled spaces and bands. Hence these stars were of a lower temperature than our sun, and here the quantity of hydrogen was greatly reduced. He had asked himself whether these facts could not be grouped together in a working hypothesis, which assumed that in the sun and stars were various degrees of "celestial dissociation" at work, which prevented the coming together of the atoms which, at the temperature of the earth, and at all artificial temperatures yet attained here, formed the metals, all the metalloids not represented in each star, and the compounds known here at present.

In answer to Professor JANSSEN,

Mr. LOCKYER said he thought it was extremely improbable that there should be any vapours which never came into the reversing layer; but of course, if this dissociation had any truth in it, there must be gold still in some part of the sun's atmosphere; but he asked whether it would not be at the extreme part of the corona rather than in the parts of the photosphere which were below the chromosphere. He had not said that gold was absent from the reversing layer of the sun, but that it had not been found there. The more the vapour occupied the lower part of the chromosphere the more conveniently would it give its spectrum; and recent researches had shown that the densities of substances which ordinarily occupied the lowest part of the reversing layer had little to do with the quantities there present.

Dr. GLADSTONE observed that a question of a very striking character had been raised; but it required thinking about for a little while before they could fairly grapple with it. It pointed to a revolution of their elementary idea in chemistry. He thought, however, that there was no impossibility whatever in what Mr. Lockyer had advanced. They knew that what they considered to be elements now were only elements to them. They did not know how to decompose them; but he imagined that there was no chemist whatever who imagined that they would never be able to decompose them. No chemist looked into the atomic weights and saw the curious relations between them without being convinced that there was some mystery behind them which would be revealed in the future. These were facts which were very suggestive indeed. If they greatly increased their power of heat and the other forces they could bring to bear on matter, they had greater power of tearing asunder those things which at the present time were elementary. The remark that there were no compounds in the reversing layer of the sun was very suggestive; and that would lead them to think that the dissociation had begun as far as our present metals, and that it was very possible that in Sirius and in some other places it might go still further. He imagined, with M. Janssen, that there were various metals which were so very indisposed to rise into vapour that they would not come into that condition.

Professor B. STEWART thought Mr. Lockyer had acted very properly in throwing out the suggestion he had laid before the section. There had been too great a tendency in men of science to hoard up their ideas till they were almost certain in their own minds that their ideas were correct. He observed that he had found that iodine had a different spectrum for different temperatures; and he

wanted to know whether this was due to mere molecular change in the iodine, or whether it was decomposed.

Dr. HUGGINS remarked that the chief character of the lines of Sirius was that they were much thinner and finer than in the other stars. The spectrum of Sirius was as full of fine lines as the solar spectrum. The subject was a vast one, and they must wait for further information upon it before they could speak decidedly upon those points to which Mr. Lockyer had so properly called attention. He wished success to all who were engaged in this field of inquiry.

Dr. DEWAR dwelt upon the temperature of the sun and the electric light, and said that in order to settle this point they must take into consideration the total radiation of the sun. During the winter he had made experiments on the vapour densities of the alkaline metals, potassium and sodium. He found that in the case of the former the vapour density was normal; whilst in the case of sodium it was abnormal, being very much higher than it ought to be. This, he thought, accounted for the large amount of light and the enormous absorptive power of sodium vapour. The denser the vapour the greater was the amount of light got in the same temperature.

Dr. SIEMENS expressed the opinion that it was impossible to estimate the temperature of the sun by the amount of heat radiated from the sun; and said that Mr. Dewar, in making the comparison he had referred to, had compared two things which had utterly different conditions. In order to determine the temperature of the sun, they had only, as a safe guide, dissociation to go by. He thought Mr. Lockyer had opened out a new field of inquiry which might lead to important results.

Mr. LOCKYER, in his reply, said he took it that they had undoubted proofs that there were stars with compounds in their atmospheres, and that there were stars with metalloids in their atmospheres, and that the temperature of those stars was not so high as that of the sun. What had been a great difficulty to him had been to discover evidence of magnesium and sodium before evidence with regard to the formation of other metals; but with respect to that point Mr. Huggins had corrected Father Secchi in a very important matter. In regard to the observations of the Egyptians, they had always been made when Sirius was just on the horizon, and the gases in our atmosphere then cut off all the blue light. Hence Sirius had been regarded as a red star.

ON THE ENERGIES OF THE IMPONDERABLES, WITH ESPECIAL REFERENCE TO THE MEASUREMENT AND UTILISATION OF THEM.*

By the Rev. ARTHUR RIGG, M.A.

(Continued from page 155).

To progress from simple to compound is a most satisfactory procedure. Adopting this plan, and dealing with only two of the thirteen elements—ignoring the others—placing the two in such a relation that their mutual affinities may be fully exercised, the law as regards these two, and (as we shall see afterwards) the energy consequent upon this law, may be made fairly evident, and utilised in manufacturing industries as well as calculated with mathematical precision.

Let two be taken—any two—say, the gases oxygen and hydrogen. Place what we may call equal quantities of each apart from all other elements. Cause them to combine. It would be soon observed—*i.e.*, if the experiment were repeated frequently—that this combination is not arbitrary, it is not at the experimenter's option. Although he may put different quantities of these gases in juxtaposition, yet by some means, and, for some reasons unknown to us, they unite only in definite proportions. If more than 11 ozs. of hydrogen be offered to 88 ozs. of

* The Cantor Lectures, delivered before the Society of Arts.

oxygen, the excess of hydrogen will be left uncombined, also the reverse.

As a case of estimation by measure, the nature of the affinities, their intensity, and the inexplicable results produce a comparison which is very striking; e.g., 24 parts by measure of common salt contain 25·8 parts of sodium and 30 parts of liquid chlorine. Such condensation—that is, the condensing, into (say) 24 cubic inches of solid matter, so much as nearly 56 cubic inches—would require the exertion of a very great mechanical force. To appreciate this, it must be remembered that the salt, the sodium, and the chlorine are all under the same atmospheric pressure, and consequently, were there not certain inter-relationships among their constituent elements, of which we know nothing, such change of volume could not be accomplished.

The exercise of affinity, although definite as regards the proportions of the bodies influenced by it, is not called into action without either previous certain surroundings or the creation of influencing surroundings, such, for instance, as the presence of moisture or heat, or light or electricity. If, for example, we take these two white powders which are here mixed together, and add a little water to them, their affinities begin to operate, and a violent effervescence takes place. Again, the states of solid, liquid, and gaseous vanish under the energies of affinity. Mr. Wills will mix two gases, and they immediately form a solid. Now we will put two liquids together, and we find that they become converted into solids. In another case you see that the contact of two bodies suffices to change their state. If a little iodine is put upon this plate, and then a little phosphorus is added, the affinities are manifested by ignition, and the solids pass into the gaseous state. Nor are changes of state and temperature the only attendant phenomena of the energy of affinity; electrical phenomena are often, if not always, present, although not always observed.

It is not improbable that, if the energy of affinity is ever measured and brought within our means of calculation, it may be done inferentially, through some of these collateral manifestations which have not yet been so carefully observed, employed, and tabulated, as their importance would seem to justify. What it is that influences these affinities is as far beyond our present knowledge as to tell what it is that influences many of the affinities of social life amongst the thirteen children. The chemist not only endeavours to establish new relationships, but also to disentangle the relationships which affinities have already established. He fails to-day, he succeeds to-morrow. With bodies thus by the energy of affinity compounded and interlaced—

—“In mazes intricate,
Eccentric, interwolved, yet regular
Then most, when most irregular they seem.”

—we all are concerned. Although we know not their laws, we do know that they partake of the Medo-Persian character—they change not—and, therefore, if once discovered, they are to be relied upon under all circumstances.

This Medo-Persian character of the laws which govern the energies of the affinities introduces into any calculation of them, when and where they are known, a precision and means of repetition, which give thus far to physical chemistry the character of an exact science. With a precision equal to that of the laws of gravity, it is found that in respect to combining proportions there is a mathematical order, perfect and exact. True, articles may be mechanically mixed in any proportions; they can be chemically combined only in definite proportions, and it is only when thus combining, in the chemist's sense of the word, that the “principle of least action” is brought into operation in affinity, and its results as economically utilised by men as the results of the energies of gravity and vitality were described to be in the last two lectures.

In mixtures the particles are still separate, and in many cases may be distinguished under a microscope. Here is

an instance. If this bottle is opened, the character of the whole contents is changed. The mixture of the atoms of the air with the nitrogen gas changed the appearance of the mass instantaneously. Again, you are all aware that coal gas burns in air, but we can also make the air itself appear to burn. In the presence of such experiments, it might become a question whether we burn gas in air, or whether we burn air in gas. Here is a cork through which are passed two small glass tubes. One of these tubes is connected with the gas of the room by this flexible india-rubber pipe, the other is open to the air. Now, light the gas issuing from the small tube. Here is a glass chimney, similar to those used with paraffin lamps. The cork has been fitted into the chimney. Place the chimney on the cork, the jet of gas burns as before. Let the supply of gas be increased, the consequence is that the chimney is soon filled with an atmosphere of coal gas; and observe, when a certain quantity of gas has entered, the flame quits the glass tube and now appears upon the air tube. Apparently air is now burning with a pale blue flame in an atmosphere of gas, whilst the gas issuing from the top of the chimney may also be ignited, and will burn in the air of the room. At the top, then, there is coal gas burning in air; and within, air is apparently burning in coal gas.

Again, for example, if gunpowder be taken and well washed, the nitre may be dissolved in hot water, and if the water be evaporated the nitre will be found as ordinary crystals; further, if heat be applied, the sulphur may be sublimed, and then pure charcoal will be left, or the sulphur may be dissolved out by bisulphide of carbon. Thus we can get the three elements of gunpowder, and find they are what they were at first. On another process of manufacture, if the nitre be fused in a crucible, and sulphur added, there results an entirely new substance—sulphate of potash; if to the heated mass charcoal be added, there is formed carbonic acid, and this, with the potash, forms carbonate of potash. No washing or warming will separate these latter combinations. They are for all purposes entirely new substances; they are no longer a mixture, as gunpowder is, in which the affinities may by a spark be called into play, but they are in a combination in which the affinities have already done their work, and that under the influence of continuous heat and without explosive violence, and, therefore, no further development of affinities, either with or without the energy of explosion, can take place.

The utilisation of gunpowder, then, is the result of a process of mixing, such mixing being designed to facilitate the action of several affinities, by placing the elements of the composition in close approximation, ready at a signal from a controlling agent to operate. It seems reasonable to say that the closer these elements are to each other the greater will be the facility with which combinations may take place, and, therefore, the more readily can the affinities be utilised. Such *a priori* reasoning is not confirmed; no simple mixture of impalpable powder, however intimately the dusty particles may have been mingled, fulfils the condition required in gunpowder. It is possible, however, so to diffuse such impalpable powder in the air of a room as that each minute portion is surrounded with an atmosphere of oxygen. If when thus diffused explosion by detonation of any group of particles takes place, the entire mass may explode. In mills for the grinding of madder this accident has happened so frequently as to require special precautions. Herein is an example of many cases in which, whilst admitting our thorough knowledge of the premises on which our reasonings are based, we are found at fault when we apply the knowledge; consequent, apparently, upon ignorance of certain even unsuggested peculiarities in the affinities involved.

Some of you may remember that in July last there was a very serious accident in a flour-mill at Glasgow. Property was destroyed to the value of £18,000 or £19,000, and nineteen lives were lost. But how it happened, or

why it happened, no one knew. The fire insurance companies deputed two scientific gentlemen to investigate the matter thoroughly, and they came to the conclusion, rightly or wrongly, that flour diffused through the air in the mill had become so uniformly or minutely mingled with the oxygen of the air, that the atmospheric contents of the room or rooms were in a state of what may be called gaseous gunpowder. The effect of a spark from the millstones or the machinery caused explosion of the aerial gunpowder by that most violent of all means—detonation. Such a conclusion of such a probable danger being only now surmised, shows how little we know of the energy of affinity. In this mill appears to be an example of the production of explosion from hitherto unsuspected sources.

We have in this bottle a diffused substance, and it is diffused in a liquid which rapidly evaporates. A piece of paper is immersed in the liquid, and we will now allow the paper to dry. When that is nearly accomplished the combustion of the paper with flame occurs, owing to the non-vaporisable solid being so minutely subdivided that the oxygen of the air is in contact with many atoms of the same material, and so energetically unites with them as to produce flame.

To apply the information already communicated to gunpowder may perhaps make as clear the influence which a more detailed knowledge of affinities would give than any other instance. The action of gunpowder is simply this: in a condensed material are many gases, we will speak of these gases as one—a gas. The utilisation of gunpowder might at first sight appear to depend upon having the largest amount of gas in the smallest solid space.

Now, without entering upon any chemical question, it may suffice to say that, in this mixture of nitre, sulphur, and carbon, are all the elements for (what we may name) the completion of the energies, though every other substance were excluded. We have here a jar of water, and if into that we put a mixture of gunpowder which has been ignited, you will find that water has no power to put an end to the combustion; it takes place as well under water as in air. From such reasoning and experiments as these, it might be anticipated that the cubic inch of gunpowder which on ignition produced the greatest number of cubic inches of gas would be the most valued. This so apparently satisfactory conclusion is very seriously in error. The amount of heat developed, and the rapidity with which the gas is formed, are important elements in guiding as to the mode of utilising the affinities called forth amongst nitre, sulphur, and charcoal. If the affinities are so intense that the development of all the heat and gas consequent upon the exercise of the affinities through the entire heap is instantaneous, then explosion of a very violent and destructive character takes place. Such an explosion for mining, and doubtless other, purposes, would entail serious loss—the rock, or the shell, would be so shivered as to be simple dust; our coals would have to be as artificial fuel, for the powder produced must, by tar, rosin, or other ingredient, be formed into lumps. To loosen and disintegrate, but not to destroy, are the general requirements for blasting or mining. If the rate at which the affinities in the mass are permitted to come into play can be regulated, and so either retarded or accelerated, then the modes of utilising them may be planned. For example, if a ball is to be sent from a gun, that law should, if possible, be impressed upon the affinities which Nature has impressed upon the energy of animal vitality. A horse accomplishes the dragging of a load by slow beginnings, a locomotive does the same, affinities must do the same. Hence, the development of the greatest intensity of affinity in the case of a gun should be progressive until it attains a maximum, and the time occupied in so doing should be determined by the rate of travel of the ball and the strength and length of the gun.

Other cases, such as the blasting of rocks, demand a very different exercise of affinities. Here the object is

simply to disturb, to unsettle, to break up; motion of the pieces to a distance is not required. Considerations such as these, simple as they may appear, are full of perplexity, consequent upon our ignorance of that in which these affinities consist.

Similar remarks apply to gun-cotton, dynamite, nitro-glycerine, litho-fraqueur, or any of the explosives which modern science has formed.

It is from an attempt to impress upon the affinities a law of time in their exercise that the various forms and compositions of gunpowder owe their origin.

We are much obliged to Mr. Abel, who has kindly lent the Society of Arts different samples of gunpowder. There is one bottle containing powder the grains of which are nearly half an inch cube; there are various other forms, the object of these various forms being to develop the affinities at a rate to be determined by the purpose for which the respective gunpowders are to be employed.

The pressure at the time of explosion has been estimated at more than 4000 atmospheres, i.e., more than 4000×15 lbs., or 60,000 lbs. per square inch. This statical pressure, being converted into a kinetic or velocity estimate, is more than 216 tons lifted 1 foot.

(To be continued.)

CORRESPONDENCE.

THE ENDOWMENT OF RESEARCH.

To the Editor of the Chemical News.

SIR,—I have just read your remarks on the above subject contained in the leading article of the CHEMICAL NEWS of Sept. 12, and with many others share the apprehension there expressed. Without claiming any degree of unnatural purity for the votaries of science, we may venture to affirm that *hitherto* no class of men have been more free from jobbery than scientific investigators. I suspect that this is owing, in a great measure, to the fact that "research is unremunerative," and therefore has no attractions for the jobbing classes, or for those who are unable to work hard and live frugally. The man who thinks it essential to his dignity and happiness to have "an establishment," and to join the race and rivalry of modern sensual expenditure, is not likely to devote himself to pure science, and science can do well enough without him.

If we are to have *prospective* payment for scientific research in the shape of fellowships, &c., we may be almost certain that dodgers, jobbers, sawners, and sneakers of all sorts will be attracted thereby, and the distribution of the scientific endowments will become as corrupt and disgraceful as the sinecures attached to our ancient cathedrals. Let us rather fall into abject poverty than sink so low as this!

At the same time, it is unquestionably true that, as science advances and the simple problems become already solved, the cost of apparatus and sacrifice of time demanded by the more recondite objects of scientific research continually increase, and place such investigations quite beyond the reach of men who have to earn their daily bread by daily teaching. As these constitute the bulk of qualified scientific workers, the pecuniary difficulty is practically the chief existing impediment to the progress of science, and consequently of civilisation. How, then, may such men be aided without being corrupted, and without a bait being held out for the enticement of "scientific Micawbers"?

I think this question may be answered at once. Let us have a fairly liberal endowment of scientific research based upon the principle of *payment for results*. This is the sound and natural principle which, by natural selection, has come into operation for the general remuneration of useful human efforts. Other men are paid for work done; why, then, should scientific workers be remunerated

otherwise? Let us suppose a case; or, to put it more pointedly and practically, I will take an actual case on which I can speak definitely. I have made and published certain preliminary investigations "On the Diathermancy and Transparency of Flame and their Consequences." These open out an extensive field of further research, which I am prevented from exploring by stronger claims than those of science, viz., duty to my own family. I cannot afford to expend £40 or £50 on apparatus, and devote £100 or £200 worth of time to unremunerative research; but if there were a market for the results of such scientific research only equal to the market which I can find for scientific teaching and scientific literature, then I might devote some of my small capital to the apparatus of research, just as I do to the purchase of diagrams and lecture apparatus, and I could also afford to give my labour in advance, just as I now do in delivering a course of school lectures payable at the close of the school term. Every other reasonable man who desires no sinecure and seeks no more than the modest income of a teacher would gladly do the same, and willingly incur all reasonable risk of failure, provided his work, when done, were fairly valued by a competent and impartial tribunal.

I have thus illustrated my argument by my own case simply because it is a truly typical one representing the actual position of the great majority of qualified scientific workmen.

If a fund for such payment of scientific research existed, the genuine worker might send in his bill with the paper communicating the results of his researches, and such a bill, after being fairly taxed, should be paid, like any other honest account, in a simple and business-like manner. The man who makes a pair of shoes supplies the want of a single individual, and is paid accordingly by the recipient of the benefit. The toiler in the workshop of science who reveals a new truth is a benefactor to the whole of mankind, has a fair and honest claim against the whole human race, and is entitled to draw a bill accordingly, which should be accepted and honoured by his own country at least. Decent gratitude and common honesty demand so much from the nation. It should be done, and may be done, without opening a door to jobbery or any multiplication of corrupt and idle pensioners.

It is just possible that a few superfine gentlemen may be shocked at such commercial treatment of science, but some considerable experience among men of all sorts has taught me that these superior creatures who affect a contempt for trade and traders are, with very few exceptions, a set of lazy humbugs, who are distinguished from honourable men of business by their unscrupulous readiness to obtain money by any means rather than honestly earning it. I therefore dismiss their objections without further notice.

Those who have the advantage of leisure and independent means may, of course, still enjoy the honourable privilege of nobly devoting themselves to the highest of human pursuits, and freely presenting their fellow creatures with the results of their industry. The more fully and publicly are the claims of science recognised, the greater will be the number of such distinguished men.

Who, then, should pay the wages of the scientific workman? The nation, undoubtedly; but before we can expect this to be initiated by Government, we must be represented and ruled by men who have sufficient scientific knowledge to be able to appreciate the importance and the claims of science. In the present state of our Universities the prospect of this is somewhat remote. In the meantime we have more to hope from private action than from Government help. In a nation where there is so much public spirit that millions are expended in "improving the breed of horses," in spite of the turf abominations with which this effort is associated, where noblemen and other millionaires can be found who will devote tens of thousands in a single season to support an opera house or a theatrical leg-show, there surely need be no difficulty in raising a sufficient fund for supplying

the immediate wants of scientific progress. I say the immediate wants, believing that it would be very demoralising to the nation if the performance of a primary national duty were permanently left to private generosity. If, however, the work were started by private effort, if its efficacy and the possibility of carrying it out without jobbery were proved, then any intelligent Minister of State might take it up, and enable the whole nation to deal justly and honourably with the most useful of its servants, instead of meanly appropriating their unrequited services, as the mighty empire of Great Britain is now so disgracefully doing.

W. MATTIEU WILLIAMS.

Woodside Green, Croydon,
Sept. 15, 1873.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Under this heading will be found an encyclopaedic list of chemical papers published abroad during the past week, with abstracts of all susceptible of advantageous abridgment. The two half-yearly volumes of the CHEMICAL NEWS, with their copious indices, will, therefore, be equivalent to an English edition of the "Jahresberichte."

NOTE. All degrees of temperature are Centigrade, unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances de l'Académie des Sciences, September 1, 1873.

On Auroræ Boreales, apropos of a Recent Memoir by M. Donati.—M. Faye.—Donati seeks the explanation of auroras in a meteorology which he terms cosmic. The phenomena are probably due to electro-magnetic currents going from the sun to the planets, their vehicle being the ether. M. Faye, hesitating to accept this view, directs attention to the forces really acting in interplanetary space. In addition to attraction there is the force producing the phenomena of comets. Might not this, operating on our earth, give rise to auroras? The effects of this repulsive force are proportioned by surfaces and not by masses. Insensible in very dense bodies, they become enormous in matter of extreme tenuity. Hence the immense comets' tails of 30, 40, and 60 millions of leagues having a direction away from the sun. These rarefied matters have a very high velocity, as if solicited by a force twelve or fifteen times greater than that of gravity. Spectral analysis shows that comets have two kinds of light; one from solar illumination, the other proper to them, and characterised by bright lines of a discontinuous spectrum, indicating incandescence of gaseous parts. The earth, too, viewed from afar would present two spectra; that of solar light, and in the obscure part near the poles the discontinuous spectrum of its auroras, boreal and austral. The author does not think the feeble incandescence of cometary matter is caused by solar heat, for the same rays do not produce such effects with us. If a screen were placed across the tail, the particles striking it would likely become suddenly incandescent. Now the nucleus is just such a screen; against which the anterior molecules of the nebulousity strike, producing heat and light; while, on the other hand, molecules not thus arrested pass rapidly behind and from the tail. Thus there is a double effect. On our globe only the extreme and very rare layers of atmosphere have some analogy to these cosmic nebulousities, but they may give rise to some of these phenomena; not tails indeed, for the greater attraction of the globe holds in the matter about it. But they might produce some feeble light-effects similar to those of comets if the repulsive force communicated to them in certain regions a considerable velocity, transferring them to other regions of our globe. The limits of our atmosphere are unknown, but the true limit will be where our

air, having become more rare than the vacuum in our best pneumatic machines, has been reduced to a medium doubtless comparable in density to the cometary nebulosities, on which the repulsive force of the sun acts. Consider this limit; it is not likely spherical. The lower layers of our atmosphere show by the barometer a well-marked minimum of pressure at the poles, and maxima which do not coincide with the equator. Temperature and radiations produce great irregularities in them; and it must be the same with the extreme layers. They probably experience on the side next the sun, the side on which they attain highest elevation, a repulsive force appearing in a slight pressure centrally, and movement at the edges. This limiting layer is thus conceived as having a less curvature, though a higher elevation, than that of the opposite side; and, as in the inferior layers (though in greater degree), presenting a depression near each pole on the right side, where the ground and inferior layers radiate least to the heavens. Then as to the edges of the hemisphere turned towards the sun. The superficial parts, reduced to extreme rarity, obey the repulsive force and are driven tangentially, acquiring considerable velocity in an hour or two. Reaching the depression near the poles they enter the vacuum and rush across it. The earth's attraction produces a strong curvature in their trajectories, and they meet the limiting surface of the atmosphere beyond the depression; and if their velocity may have reached several hundred metres per second, the incessant shock of these mobile particles against the fixed will give rise to light. The slight illumination which will be visible to us in a limited part of the heavens will have the characters of gaseous incandescence. This phenomenon will not occur equally all round the globe. In regions a little removed from the poles there is no vast depression to cross; the molecules in their passage encounter the resistance of a continuous layer, and cannot acquire the same velocity as at the poles. Hence the light will mostly be produced at the poles, and especially at the pole actually deprived of solar light. The author's purpose is not to assert this as the veritable cause of polar auroras, but to show that, apart from the mysterious causes one is tempted to invoke, there is besides Newtonian attraction a real cosmic force which must play some part in our meteorology, and which is connected very simply with the sun itself, and especially with the variable state of his surface.

Note on Siemens's Bobbin.—M. Pellerin.—The chief disadvantage of it is that it develops a considerable amount of heat, and thus work is lost. The heat probably arises in most part, from currents developed by the movement in the metallic mass forming the core. Such currents, which are parallel to the axis of rotation, may be obviated by forming the core of discs of *soft insulated iron*, the combination of which in a sufficiently solid manner is not an insurmountable difficulty.

Changes of Form and the Spectrum of the Comet (1873) IV.—MM. Rayet and André.—On the 26th and 27th August the comet had a circular form of about 6 min. diameter, with luminous condensation in the centre. Its spectrum consisted of three bright lines in green, yellow, and blue, the first being longer than the two others. On the 29th and 30th its diameter was 8 min., and it showed a tail of 25 min. directed away from the sun, and inclined at about 47° to the direction of diurnal motion. The head, still round and with a brighter nucleus, gave a spectrum of three luminous bands as before, but also a faint continuous spectrum. Some peculiarities in the green band are noted. Drawings of the comet are given.

Form of Martial Seas Compared with that of Terrestrial Oceans.—M. Meunier.—According to one theory of sidereal evolution Mars is an older planet than our earth, and now presents features which our earth should present later. The author finds a new indication of the greater age of Mars in the form of the oceans on the planet, which are described by Mr. Proctor as of

bottle-necked shape—long and narrow passages. Now if one takes a marine map, such as that of the North Atlantic Ocean, and traces successive horizontal curves for increasing depths, one perceives that these curves tend progressively to limit zones, the form of which is more and more elongated. At 4000 metres, for example, one obtains forms comparable in all points to those of the Martial seas described. Hence, if we suppose the Atlantic absorbed by deep masses actually in course of solidification, so that the surface of this ocean sinks to 4000 metres, we should have a small surface covered with water, and a narrow elongated form of sea exactly as in Mars.

Metalliferous Veins of Cornwall; the Rich Portions of the Veins, the Structure of Such Portions, and their Relation with the Direction of the Stratigraphic Systems.—M. Moissenet.—The author draws the following conclusions:—The parts of the vein whose incline approaches most nearly to a vertical direction are the most productive. The rich portions are commonly, in Cornwall, enclosed in a gangue of moderate hardness. Most frequently the metalliferous bands or columns incline in the same direction as the gangue. The rich portions are frequently disposed according to the direction of the stratigraphical system to which the initial fracture of the vein is related.

Gazzetta Chimica Italiana, Anno III.,
Fascicolo VII. e VIII., 1873.

Researches on the Nature and Constitution of Tannic Acid.—Ugo Schiff.—The author reviews the previous labours of Berzelius, Strecker, Robiquet, Rochleder, Hlasiwetz, Löwe, &c. He then examines the reactions of tannic acid with the oxychloride of phosphorus and with arsenic acid. The composition of aceto-tannic acid he gives as—

Carbon	54.2
Hydrogen	4.4
Acetyl	41.5

100.1

corresponding to the formula $C_{14}H_5(C_2H_3O)_5O_9$. He concludes his interesting paper with an examination of the ellagic and rufigallic acids.

Butyric Acid Generated in Fermentation.—G. B. Grillone.—The author made an extract 5 kilos. of rice in 60 litres of boiling water. After twenty-four hours 60 grms. of malt were added, steeped in 2 litres of milk, 1 kilo. of minced flesh, and 2 kilos. of white chalk. The whole was allowed to ferment in a covered wooden vessel at the summer temperature (25° to 30°). When the development of gas had ceased the liquid was raised to 80°, filtered, mixed with carbonate of soda as long as a precipitate was produced, the carbonate of lime filtered off, and the filtrate concentrated to a small volume and mixed with sulphuric acid, when a considerable quantity of crude butyric acid separated, and was freed from accompanying products by fractional distillation.

Action of Aldehyds on the Bisulphite of Naphthylamin.—Dr. G. Papasogli.—Benzoic aldehyd was added to a hot aqueous solution of bisulphite of naphthylamin. The liquid became turbid, and small white crystals were deposited, soluble in alcohol, but insoluble in ether and water. They contain—

Carbon	61.63
Hydrogen	5.13
Sulphur	9.66
Nitrogen	4.27
Oxygen	19.33

100.02

corresponding to the formula $C_{10}H_9N.H_2SO_3.C_7H_6O$. This benzoyl-bisulphite of naphthylamin loses all its sulphurous acid at a gentle heat, yielding a fusible resinous compound very soluble in ether, moderately soluble in

absolute alcohol, but insoluble in water. The ethereal solution on treatment with ordinary alcohol deposits a whitish yellow crystalline powder containing—

Carbon	88.32
Hydrogen	5.62
Nitrogen	6.06

100.00

corresponding to the formula $C_{10}H_7N, C_7H_6$.

Action of Amides on Phenol.—Dr. Icilio Guareschi.—The author has studied the behaviour of benzamid and acetamid on phenol, and that of benzamid on the salicylate of methyl.

Action of Chloroform on Phenate of Potassa.—Dr. J. Guareschi.—The author, wishing to find a sensitive reaction for detecting the presence of phenol evaporated to dryness, a solution of phenol to which potassa had been added, and the residue while still warm was mixed with chloroform; a splendid purple-red colour was immediately developed. The potassa must not be in excess, nor the temperature very high. The reaction is decisive with 0.1 milligram of phenol. The colour is probably due to the formation of rosolic acid.

Synthesis of Conüna.—Ugo Schiff.—This paper is taken from the *Annalen der Chemie und Pharmacie*, vol. clix., p. 88, with some additions by the author.

Analysis of a Sulphurous Water from Messina.—G. Mazzara.

Revue Hebdomadaire de Chimie Scientifique et Industrielle, par Ch. Mène, No. 33, 1873.

The only chemical paper in this number is the description of an apparatus for the analysis of gases, patented by M. H. Orsat. A description would be unintelligible without its accompanying woodcut.

Reimann's Färber Zeitung, No. 32, 1873.

In the continued notice of the Vienna Exhibition we find mention of Scheuermann's birling-inks, as distinguished for excellence in quality. We find receipts for dyeing and finishing plushes; for a bright green on woollen piece-goods, flannel, and wool; a medium green on woollen cloth; a dark green for shot-goods; a silver grey, a drab, and a bright salmon on cotton yarn; a green on wool and woollen yarn with Nicholson's blue. This may be produced by boiling the 100 lbs. of goods, previously dyed a medium blue with 1½ lbs. sulphuric acid, 3 lbs. alum, and about 1 lb. picric acid till the required shade is obtained. A faster green can be obtained by boiling the same weight for an hour with 3 lbs. alum, 2 lbs. tartar, and 12 lbs. fustic, or young fustic. The latter gives a brighter, but the former a faster shade. There are also receipts for an olive on wool, a dark blue and a bright brown on woollen piece-goods. In the garment, or old materials department, are receipts for a pansy on silk, and a brown on mixed silk, such as silk and satin ribbons.

The following formula is proposed for a chrome yellow on calico:—The pieces are saturated with a solution of sugar of lead (1½ lbs. per gallon), dried, printed with colour composed of alizarin, red liquor, and acetic acid thickened with starch, steamed for ninety minutes, aged for two days, passed through a solution of 3 ozs. chromate of potash per gallon, handled in a weaker solution of the same salt, washed and brightened with soap. "Anthracen blue" is still flourishing, at least on paper. According to the inventor 25,000 grs. of anthracen yield only 2.5 grs. of this mysterious colour, whence Dr. Reimann calculates its cost at 20,000 six-dollars (£3000) per lb. The inventor of this same colour gives the following receipt for a black on linen yarns. "To 100 ells take 4 lbs. catechu, 4 ozs. sulphate of copper, and 1½ lb. potash, and give it a couple of turns at a brisk heat. It is then worked for half-an-hour in a boiling bath of 5 to 6 lbs. of logwood, and 1½ lbs. of

sumac, blackened in the same lot with 1½ lb. copperas, rinsed, finished with starch and tallow or lard (1), dried, and well calendered."

MISCELLANEOUS.

Assay of Crude Phenic Acid.—Hager gives the following process for the assay of crude phenic acid:—5 c.c. of the sample are taken and shaken up with 3 c.c. of a mixture of caustic potash (sp. gr. 1.34) and of alcohol at 95°. (The respective quantities of potash-lye and of alcohol are not stated.) 5 c.c. of essence of petroleum are then added, and the whole shaken again. It is then allowed to settle. When the liquids have separated the volume of the lower stratum is read off. The increase in its bulk shows the amount of actual phenic acid present in 5 c.c. of the sample. The lower stratum consisting originally of the alcoholic potash liquor its bulk was 3 c.c., and all increase is due to the quantity of phenic acid. Schöedler proposes a method of assay based upon the fact that phenic acid when heated combines with sulphuric acid, whilst the latter carbonises the tarry products, disengaging a certain quantity of sulphurous acid. If we add to the products of this reaction of sulphuric acid with crude phenic acid water, and then carbonate of baryta or litharge, there is formed a soluble sulpho-phenate and an insoluble sulphate, which carries down with it the carbonaceous matters, whilst the oily substances separate themselves in virtue of their insolubility. All that is then needful is to precipitate the solution of sulpho-phenate of baryta with sulphuric acid, and to deduce the quantity of phenic acid from the amount of sulphate of baryta obtained. The following are the details of the process:—2 to 3 grms. of the sample in question are taken and heated in the water-bath to volatilise any alcohol that may be present. An equal quantity of concentrated sulphuric acid is then cautiously added, and the mixture is then exposed to a temperature of 50° to 60°. The liquid is then diluted, mixed with carbonate of baryta or litharge in excess, and filtered by decantation. The filtrate presents a yellowish colour. It is decomposed by dilute sulphuric acid; the precipitated sulphate of baryta or of lead is collected and weighed, and the amount of phenic acid is calculated.—*Moniteur Scientifique*.

PATENTS.

ABRIDGMENTS OF PROVISIONAL AND COMPLETE SPECIFICATIONS.

Improvements in purifying sewage and treating products obtained therefrom for the production of manure. Baldwin Latham, 7, Westminster Chambers, Victoria Street, Westminster, Middlesex. January 28, 1873.—No. 331. This invention consists in utilising the precipitate obtained from sewage in the "alumina," "phosphate of alumina," and other phosphatic processes, and the "magnesia" and "iron" processes for treating other sewage for the production of manure. The said precipitate is first dried, and after standing some time is treated with sulphuric or other acid, so as to convert the alumina in sulphate and sesquisulphate of alumina and the phosphates of alumina and lime into superphosphates, and also to carbonise some of the organic matter. The compound so treated is then mixed with the sewage, together with sufficient alkali to neutralise the acid, whereupon the resulting alumina, phosphate of alumina, and phosphate of lime, are precipitated, and, at the same time, the flocculent deposit formed drags down the suspended matters in the sewage, while the humus, mould, and carbonised matter of the compound combine with some of the ammonia. The deposit thus obtained may be used as a manure, or it may be dried and treated and be again applied to other sewage, in the above-described manner, in order to obtain a rich manure. The solid matter may be first removed from the sewage by the apparatus described in the petitioner's specification, No. 809, of 1869.

Improvements in the means employed for freeing glass from carbon, grease, or other substances that may adhere to its surface. James Augustine Hartley Toulson, manufacturing chemist, and Thomas Harmer, Leeds. January 28, 1873.—No. 335. Fluoric acid in combination with muriatic or nitric acid, and sometimes other acids; or fluoric acid with water; sometimes a powder is used composed of pumice-stone, slaked lime, salts of tartar, Derbyshire spar, powdered soap, sugar. The invention is particularly applicable to railway-station or other large roofs.

Improvements in lamps and apparatus for burning mineral oils or other inflammable liquids. Joseph Sokolnicki, Clinchor, near Castillon, France. January 28, 1873.—No. 336. This invention consists in com-

binning with the burner of the various forms and arrangements of lamps an evaporating tube, for the purpose of keeping up the supply of vapour from the mineral oils or essences or other inflammable liquids, and thereby prevent the light from becoming small or extinct.

Improvements in lamps for burning heavy oils. John Henry Johnson, 47, Lincoln's Inn Fields, Middlesex. (A communication from Robert Hitchcock, John Morton Sigourney, and William Van Vranken Rosa, all of Watertown, Jefferson Co., N.Y.). January 29, 1873.—No. 356. This invention is directed to the burning of heavy oils in lamps in such manner that a brilliant flame without smoke may be produced without requiring the use of a chimney. To the accomplishment of this object I have found the following instrumentalities requisite:—First, passages or ducts through which air may be conducted both to the exterior and interior of the flame; secondly, mechanism for impelling currents of air through these passages to both the exterior and interior of the flame; thirdly, a deflecting cap or cone placed over the wick with an aperture for the passage of the flame, and so shaped as to direct the external impelled current of air to impinge upon the exterior of the flame.

An improved explosive powder or compound, and the mode of preparing the same. H. H. Murdoch, patent agent, 7, Staple Inn, Middlesex.—(A communication from Baron Victor de Rutenberg, Paris).—January 30, 1873.—No. 360. This invention consists in mixing randanite with nitro-glycerine in order to produce an improved explosive powder. Randanite, which is a hydrated silica, was first discovered at Randanne, in France. According to this invention the randanite is first dried and then roasted at a light red heat. It is then reduced to powder and sifted, and is ready for use as an absorbent for nitro-glycerine. Should, however, the randanite used be very impure, it should before being treated as described be washed in an acid solution. The improved explosive powder is made by mixing the prepared randanite with nitro-glycerine by pouring the nitro-glycerine gradually upon a quantity of the prepared randanite upon a surface coated with gutta-percha or soft metal, and stirring the mixture with a wooden spoon or slice. Or the mixing might be effected in a mixing machine.

Improvements in the manufacture of manures. John McDougall, of the firm of McDougall Brothers, manufacturing chemists, Manchester and London. February 1, 1873.—No. 393. This invention has for its object improvements in the manufacture of manures. I treat phosphatic substances with sulphuric acid to render them soluble and remove the soluble constituents (either whole or in part) by washing, filtration, or other convenient method, and into the resulting solution I pass liquids, gases, vapours containing ammonia, and the resulting product may be concentrated or dried by exposure or heat. Or, after passing ammonia into the resulting solution as herein described, I allow the precipitated phosphate of lime to subside and separate the liquid, which can be evaporated into a salt. The precipitated phosphate can be dried for use or incorporated in the semi-liquid state into the manufacture of superphosphates as hereafter described. The solution obtained as herein described may be used for the removal of ammonia in coal-gas or other gases arising from the destructive distillation of carbonaceous substances, by employing it in the ordinary washers or scrubbers in use in gas-works, or by other convenient method. I also treat phosphatic substances with hydrochloric acid in any desired quantity to render them soluble; if sufficient of the acid has been added to convert the phosphate into the liquid state, any insoluble residue may or may not be removed by subsidence or other convenient method; and into the mass or liquid I pass gases or vapours containing ammonia other than coal-gas. The resulting product can be concentrated by heat or exposure. Or, in treating the phosphatic substances with hydrochloric acid as above described, I take care the acid is of reduced strength, or, if acid of full strength is used, the resulting solution may be diluted, so that, after passing in the gases or vapours containing ammonia, the resulting solution shall not be too dense to allow the soluble phosphate that has become changed into precipitated phosphate to subside, so that the liquid may be run off and evaporated into a salt, and the precipitated phosphate dried for use. In the manufacture of superphosphate of lime for manure, when sulphuric acid is used, it is customary to dilute the acid with water when bringing it into contact with the phosphate to be acted upon, by which means a drier product is obtained than if acid alone were employed. This water, either whole or in part, I substitute with liquids or semi-liquids containing ammonia or other useful manurial ingredients, and so utilise them, at the same time obtaining a manure of sufficient dryness. If the liquid used requires the addition of an acid for its proper utilisation, the acid must be added to it before using, or extra acid added to the phosphate. After the removal of the soluble constituents from the phosphatic substances treated with sulphuric acid as already described, the residue will consist to a large extent of sulphate of lime, this sulphate of lime, or sulphate of lime obtained by other methods or in a natural state, or chloride of calcium, I treat with liquids containing ammonia, and whilst agitated pass in carbonic acid, which causes the decomposition of the sulphates or chlorides, and liberates the acids to combine with the ammonia. After subsidence, I separate the resulting solution and evaporate it into a salt. The carbonic acid generated in the treatment with an acid of phosphatic substances containing carbonate of lime may be utilised for this purpose, or may be derived from other convenient source. When it is desirable to convert the precipitated phosphates obtained by the foregoing process again into soluble phosphates, either wholly or in part, I add sulphuric or any suitable acid to effect this purpose.

NOTES AND QUERIES.

Water Free from Ammonia.—Being in frequent use of Wanklyn and Chapman's "ammonia process" in water analysis, I have found the preparation of "ammonia-free" water, for comparison, to be a

tedious and troublesome operation, especially if required in large quantities; an accidental discovery has, however, relieved me from further inconvenience upon that score. I have in my laboratory a copper drying oven heated by steam from a boiler. The oven is secured against excessive radiation by an outer case of wood, but, notwithstanding this, there is a considerable amount of condensation going on in the copper jacket of the oven, and I find that the resulting water is free from every trace of NH_3 ; thus I have a constant supply of water, which only requires cooling to render it fit for even the most delicate determinations. The high temperature at which the steam is condensed is evidently the cause of the purity of the water.—W. F. K. SROCK, F.C.S., Laboratory and Assay Office, Wooler Street, Dartington.

TO CORRESPONDENTS.

H. H.—"Jetoline" is a peculiarly made aniline black. Methods for using it in photography have been described in photographic periodicals.

A. P.—The following is the prescription for hydrosulphite of soda, as given by Schützenberger and Rislér:—Allow 30 grms. of bisulphite of soda at 30° Baumé to act on zinc turnings, air being excluded. After about half an hour, 50 to 100 grms. of milk of lime are added containing 200 grms. of quick-lime per litre. It is then diluted with 5 litres of water, shaken up, the clear liquid decanted, and preserved in small bottles completely full, well stoppered, and inverted under water.

J. Wilson.—As the wool has been already treated with sulphuric acid, it is not likely that any substance will, without either destroying the woollen fibre, or altering it so as to render it worthless except as a manure, discharge the dark colour from the wool, which cannot be treated with chlorine or similar agents; still you might try the action of sulphurous acid gas, which might to some extent bleach the dark coloured wool, which appears, however, to have been dyed with fast colours.

London: 3, Horse-Shoe Court, Ludgate Hill, E.C.

Two Courses of Lectures on Geological MINERALOGY will be given at KING'S COLLEGE, LONDON, by Professor TENNANT, to which the public are admitted on paying the College fees. One Course is given on Wednesday and Friday mornings, from 9 to 10 o'clock, commencing Wednesday, October 8th, and terminating at Easter, 1874. The other Course is given on Thursday evenings, from 8 to 9, commencing October 9th. The Lectures are illustrated by a very extensive collection of specimens.

Practical Instruction in Mineralogy and Geology is given by Prof. TENNANT, F.G.S., at his residence, 149, Strand, W.C.

PRACTICAL CHEMISTRY.

Laboratory, 60, Gower Street, Bedford Square, W.C.

Mr. Henry Matthews, F.C.S., is prepared to give instruction in all branches of PRACTICAL CHEMISTRY, particularly in its application to MEDICINE, AGRICULTURE, and COMMERCE.

The Laboratory is open daily, except Saturday, from ten to five o'clock; on Saturday, from ten till one o'clock.

Mr. Matthews is also prepared to undertake ANALYSES of every description.

For Particulars and Prospectuses, apply to Mr. Henry Matthews, the Laboratory, 60, Gower Street, Bedford Square, W.C.

Royal Polytechnic Institution, 309, Regent Street.—Laboratory (entirely re-fitted) and Class-Rooms are now open.

ASSAYS, ANALYSES and Investigations connected with PATENTS conducted.

Pupils received for Class and Private Study. Special facilities are offered to persons preparing for GOVERNMENT EXAMINATIONS.

Classes are now forming for Practical Study in CHEMISTRY, STEAM, and PHYSICS.

For particulars, apply to Professor E. V. GARDNER, F.A.S. M.S.A. at the Institution.

BRITISH ASSOCIATION FOR THE ADVANCEMENT
OF SCIENCE.

BRADFORD MEETING, 1873.

SECTION B.—CHEMICAL SCIENCE.

PRESIDENT, DR. W. J. RUSSELL, F.R.S.

"*The Purification and Utilisation of Sewage.*"—Mr. R. B. GRANTHAM, C.E., brought up the Report of the Committee of the Association on the Treatment and Utilisation of Sewage. The meetings of the Committee had been attended by Mr. Grantham, Professor Corfield, Mr. J. H. Gilbert, Mr. W. Hope, and Professor A. W. Williamson. The Committee stated that it had continued that part of the inquiry for which it was particularly re-appointed last year, viz., the examination of the typical case of sewage farming at Breton's Farm, near Romford. Tables similar to those of last year were again supplied. An analysis had been made of the soil of the farm, showing a considerable increase in the amount of nitrogen and of phosphoric acid. A further examination had been made of the sewage farm at Earl's Wood, with more satisfactory results than before. Dr. Gilbert had again furnished a note on the dry earth system. Whitehead's process had been for a few days at work on a considerable scale at Enfield. The Local Government Board had obtained returns of loans for sewage farms, conducted by local authorities. The information in those returns would be valuable if exact. A radical defect in them was that there was no separation of capital from working expenses, and the cost of land was lumped with that of the works.

Mr. HOPE read an elaborate report on Breton's farm at Romford. Systematic observations had been continued and summarised in tables corresponding to those of last year. Many of the results thus contrasted were instructive; but the tables, although themselves only summaries, were so voluminous that it was impossible adequately to describe them. The points of chief importance were that the effluent water was slightly purer, thus exploding the nonsense sometimes talked about land becoming "sick" of sewage, that an analysis of samples of the soil taken in April, 1873, at the same part of the farm as the samples were taken from for the analysis of 1870, prior to the application of any sewage, showed very appreciable quantities of phosphoric acid, ammonia, and nitric acid, when valuable manures were almost indeed practically absent in the same soil in 1870. The committee also found that the population of Romford had been largely overstated by the Local Board, and that instead of between 7000 and 8000 persons feeding the sewers there were only about 4600 persons in all. This, of course, gave a very different complexion to the agricultural results, and, amongst other things, gave the new and important fact, that in the case of the town the sewage of the population, including, of course, kitchen and wash-house slops, and that due to horses and to live-stock on market days, contained 13·14 lbs. of nitrogen per head per annum.

Professor CORFIELD gave the substance of an abstract of all the reports which had been presented to the Association by this Committee since its first appointment. The final opinions of the Committee were in substance as follows:—

I. All conservancy plans, including midden, heap, and cesspool systems, dry ash, and dry earth closets, pail closets, &c., are quite incompetent as solutions of the general question of the removal of the refuse matters of a population; they only deal with a small part of the liquid

manure; towns which resort to one of them require to be sewered, and the sewage requires to be purified. The manure produced is in all cases (except in that of pimple pails or tubs, where no extraneous materials are added) poor, and will only bear the cost of carriage to a short distance, taking into consideration the cost of collection, that produced by the dry earth system being, even after the earth has been used three times over, merely a good garden mould. Moreover, these plans all violate one of the most important of sanitary laws, which is that all refuse matters which are liable to become injurious to health should be removed instantly and then be dealt with afterwards. With all these plans, it is an obvious advantage on the score of economy to keep the refuse about the premises as long as possible, and the use of deodorants of various sorts, or even of disinfectants, proves that this is the case, and that these systems all depend upon a fallacious principle. They should therefore be discouraged as much as possible, and only resorted to as temporary expedients, or with small populations, in very exceptional instances.

II. The water-carriage system, on the other hand, is based upon a sound principle, that of removing all the refuse matters at once and in the cheapest possible manner by gravitation, and ought to be resorted to in all but the most exceptional cases. The opinion of the committee that all sewers should be made of impervious materials, and that separate drains to dry the subsoil should be constructed where necessary, has already been most emphatically expressed. The freest possible ventilation of sewers, house drains, and soil-pipes, in order to prevent accumulations of foul air, is also essential. With regard to the utilisation of sewage, the Committee has come to the conclusion that the precipitation processes that it has examined are all incompetent, and necessarily so, to effect more than a separation of a small part of the valuable ingredients of sewage, and that only a partial purification is effected by them. Some of them may, however, be useful as methods of effecting a more rapid and complete separation of the sewage sludge.

The upward filtration process only effects a clarification of the sewage, and is, therefore, no solution of the question.

Weare's charcoal filtration process, as carried on at Stoke-upon-Trent Workhouse, did not give satisfactory results, the effluent water being in effect weak sewage; an opportunity will, however, soon be given for an examination of this process in a modified form on a much larger scale at Bradford, and under more favourable conditions. Intermittent downward filtration through soil has been shown at Merthyr Tydfil to afford a means of purifying the sewage under favourable conditions, but it cannot be said to be a method of utilisation except to a partial extent, as the investigations made by the Committee showed that the effluent water contained as much nitrogen as was originally in solution in the sewage, but mainly as nitric acid, instead of as ammonia and organic nitrogen; and there can be no doubt that the process will prove useful as an adjunct to irrigation, or where a sufficient amount of land for irrigation cannot conveniently be got.

By properly conducted sewage irrigation a solution is afforded to the question of sewage utilisation; it has already been stated that a precipitation process, or some clarifying process, may be found useful; in all instances it is essential that the land should be well underdrained, and that the sewage should all pass through the soil, and not merely over it; otherwise, as has been shown, it will only occasionally be satisfactorily purified. The catch-water, or, as the Committee has termed it, the "super-saturation" principle, is not defensible either on agricultural, chemical, or sanitary principles; an irrigation farm should therefore carry out intermittent downward filtration on a large scale, so that the sewage may be always thoroughly purified, while at the same time the maximum of utilisation is obtained.

It is certain that all kinds of crops may be grown with sewage, so that the farmer can grow such as he can best sell. Nevertheless, the staple crops must be cattle food, with occasional crops of corn; and it is also certain from the analysis of the soil that it has become very much richer, and that the manurial constituents of the sewage accumulate in it. Cattle should be fed on the farm, which leads to a vast increase in the production of meat and milk, the great desiderata of the population producing the sewage. Thus the system of farming must be specialised and capital concentrated, the absence of which conditions has proved a great barrier to the satisfactory practical solution of the sewage question.

The Committee has not been able to trace any ill effects to the health of the persons living around sewage farms, even when badly conducted; nor is there any proof whatever that vegetables grown thereon are in any way inferior to those grown with other manure. On the contrary, there is plenty of evidence that such vegetables are perfectly suited for the food of man and beast, and that the milk given by cows fed on sewage grass is perfectly wholesome; thus Mr. Dyke, Medical Officer of Health of Merthyr Tydfil, states that since the abundant supply of milk from the cows fed on irrigated grass the children's mortality has decreased from 48, 50, and 52 per cent of the total deaths, to only 39 per cent, and that so far from diarrhoea having been made more prevalent by the use of sewage cabbages, "last year the Registrar-General called attention to the fact that diarrhoea was less prevalent in Merthyr than in any place in England and Wales;" and he expressed his belief in "the perfect salubrity of the vegetable food so grown."

With regard to the assumption which has been made that entozoic disease would be propagated by irrigation, all the evidence that the country has been able to collect, and more especially the positive facts obtained by experiments, are against such an idea, and the Committee is of opinion that such disease will certainly not be more readily propagated by sewage irrigation than by the use of human refuse as manure in any other way, and probably less if the precaution be taken of not allowing the animals to graze, but always having the grass cut and carried to them.

"*The Sewage of Manufacturing Towns.*"—Mr. W. T. McGOWEN (the Town Clerk of Bradford) read a paper on the above subject, in the course of which he said:—"There are few subjects connected with the management of large towns which cause greater embarrassment than that of the disposal in a satisfactory manner of their sewage, especially when it contains the refuse of establishments engaged in the manufacture and dyeing of textile fabrics, where the surrounding district is extensively occupied with dwellings, or the surface is affected by serious variations of altitude. Local authorities are frequently charged with supineness in relation to this branch of their duty; but they are not open to the imputation, and if they were there are influences in operation sufficiently active to forbid all chance of their being allowed to slumber. As a rule they are willing to incur any reasonable trouble or expenditure. The difficulty lies in another direction; they are in perplexity as to what is the proper course for them to adopt; and in the whole range of inquiry to which the labours of the British Association are directed, nothing would confer a greater boon on the country than the settlement of this question in a thoroughly practical manner. The stages by which the matter has assumed its present aspect do not admit of much controversy; the growth of population and the evils arising from neglect of sanitary requirements.

Mr. McGowen then went on at some length to speak of the stages by which the matter has assumed its present aspect; of the difficulties that have to be encountered by large towns; and of the recent attempts to legislate upon the subject. He then referred to the report obtained last session by the President of the Local Government Board, showing what has been done in reference to the purifica-

tion of sewage in specified parts of the country. The processes employed are arranged under the heads of Sewage Farms, as adopted in 45 towns; Filtration, as adopted in 54 towns; and Precipitation, as adopted in 30 towns. These do not comprise every place where endeavours are made to deal with sewage, because Birmingham, which has been severely tried, is not even mentioned. The report shows conclusively that the whole subject is yet imperfectly understood, and that what is done is chiefly of a tentative character. The largest town in the list, Leeds, relies on precipitation; but this has been in operation only one year there; and Wilsden, the town which has longest tried a sewage farm, that is from thirty-five to forty years, cannot have achieved a great success, because it is stated in the report that the sewage is merely run over the land, and that on one occasion, when it escaped into the river Peuk, it led to complaint. In none of the cases is sewage in very considerable quantity subjected to treatment. It would be unfair to the gentlemen who advocate the irrigation system to test their views by what is done at Wilsden, because it is admitted by those whose judgment is to be respected that for sewage farms to be efficient the subsoil of the land must be prepared to a proper depth, and with proper material, or not only will the rainfall fill the land with water, and thus reject the sewage, but the sewage will fail to answer the intended purposes of imparting its fertilisers to the earth and the roots of plants, and then passing away purified. On the other hand, it would be equally unfair to local authorities of places like Bradford, and Leeds, and Halifax to assert that what may answer well at Romford or Worthing must necessarily be applicable to them. The difficulties of applying irrigation schemes to the manufacturing towns of this district are most serious. Sir William Denison, when he sat on the Rivers' Commission at Bradford, being asked how much land would be required for the irrigation of the sewage of that town, replied "Ten thousand acres." There is no such quantity of land to be got in the district except at much higher levels than the sewage; land is extremely dear: and being more or less occupied with good dwellings irrigation would lead to endless litigation for nuisances. Any application to Parliament for power to make a large sewage farm in the neighbourhood would share the fate of the Birmingham bill. The irrigation, if resorted to, must therefore be at a great distance, and for every yard of land required for conduit extortionate claims for compensation would be set up; the cost, including arbitration expenses, would be absolutely ruinous; and, moreover, the waters would be thus withdrawn from their natural course, where they are indispensable, the streams they now supply, though with an objectionable contribution, would cease to exist, and the industries of the district would be paralysed. Bradford, having been taken in Chancery, agreed to use her best efforts to defecate the sewage of the town. Her case is a good illustration of the capricious state of the law. The sewage is discharged into a stream (the Bradford Beck) for the condition of which she is not answerable; and Dr. Letheby, on a comparative test of the impurity of the sewage and the impurity of the beck, found the latter the worse in the proportion of three to two. The sewage actually improved the waters of the beck. The Corporation, however, could not deny that they sent sewage into the river Aire. They therefore submitted to the above arrangement, and they have spared neither pains nor money to perform it. They carefully considered the best course they could adopt. For the reasons already given, they found sewage farming to be impossible, and they also found that precipitation by the lime process would plunge them into increased trouble, for although the sewage could be cleansed, such an amount of semi-liquid products would be thrown upon their hands as would be beyond their control; the daily discharge of the sewage being about 5,000,000 gallons. After full inquiry it appeared to them the best thing they could do was to contract with the Peat Engineering

Company, by which, under the management of Mr. Dan-
chell, the Company undertake to defecate the sewage,
the Corporation providing the requisite works. Without
entering into minute details, the process of the Company
may be briefly described as being partly filtration and
partly subsidence by means of a catchment chamber by
tanks and other appliances, to which is conjoined a
system of purification by peat charcoal, the power of
which constituent over the offensive properties of impure
air or water is indisputable. This complex operation is
capable of sending off effluent water far beyond the
standard of purity imposed on the Corporation, whilst the
residual products are made inodorous by the peat char-
coal, and are quickly solidified by the mechanical admix-
ture of other ingredients, so as to form a portable manure.
From what has already been stated with reference to
Bradford, it follows that whether the plan which the
authorities have adopted shall prove eminently successful
or a complete failure, the effect upon the river Aire will
be unappreciable, not only on account of the worse con-
dition of the beck, but also from the fact, to be seen on
reference to the accompanying plans, that there are many
other places sending their pollutions into the river besides
the Bradford Beck. The authorities of the neighbouring
districts are fully sensible of their position, and the best
proof of their desire to provide an efficient remedy is that
in 1871 they united in framing a bill for the conservancy
of the Aire and Calder rivers. Instead of meeting with
support from those who had cried out against pollution,
the bill received their strongest opposition, thirty-three
petitions being presented against it. Notwithstanding this
hostility, the promoters would have stood their
ground, more especially as Mr. Secretary Bruce had
promised that the bill should, so far as the Government
were concerned, at least have a fair hearing in committee.
This promise was honourably fulfilled, on an attempt
being made by some of the petitioners to postpone the
second reading for six months. The manufacturers at
Halifax, who are all potent in that borough, then
threatened the Corporation that if they spent any public
funds on the bill the Queen's Bench would be applied to
for a mandamus. The Halifax Corporation were thus
compelled to stay their hand and withdraw. Hudders-
field was on similar grounds compelled to follow suit;
Leeds was in equal difficulty; and Bradford, being
situated only on the Aire, had no case for Parliament as
to the Calder, and so the bill dropped. The principle of
that bill embodies the result of the care bestowed on the
question at the time by the promoters. It is framed upon
a broad and liberal basis. Nothing has since occurred
to show that it was wrong, and the scheme, with one
exception, is now submitted to the consideration of this
meeting as that best suited for this part of the country,
and equally applicable elsewhere.

Having described the general features of the Aire and
Calder Conservancy Bill, Mr. McGowen said—The advan-
tage of the system by which the standard of purity would
be obtained under such a scheme as that proposed by the
Conservancy Bill as against that proposed by the Govern-
ment bills is, that instead of laying down a hard and fast
rule, applicable in some places, but inapplicable in others,
an elastic arrangement is provided, which can be rendered
suitable for every district and its trade. In fixing the
standard some regard should in justice be paid to the
condition of the outfall river; otherwise, as was pointed
out by noble lords in committee, a manufacturer might be
called upon to return water better than he got it, and
better than the river into which it is discharged. A high
standard might be found impracticable at the commence-
ment of the conservancy, and some degree of forbearance
might therefore be necessary; whilst after a given interval
the standard might safely be made more severe; or, on
the other hand, if found to be too stringent, and con-
sequently mischievous, it could be rectified without the
expense and trouble of a fresh Act of Parliament every
time a change was wanted. The prime object of the

scheme was to put all the manufacturers of the district on
the same footing with each other, and render the burden
of purification as light on their shoulders, compared with
competitors elsewhere, as is possible. No man can fairly
deny that the treatment of the sewage of large manu-
facturing towns is a grave subject. It may be that all
tried systems will fail on account of the enormous quantity
of sewage to be dealt with, and the limited superficial
area of England available for its application. Should this
happen, the only remedy would appear to be for the
Government to undertake the construction of main outlets
to suitable points on the coast, where the refuse could
conveniently be used in fertilising wastes of sand, or be
got rid of in the sea, leaving the local authorities the duty
of conveying their sewage to these outlets. This, however,
would necessitate the construction of reservoirs, to re-
plenish the streams whence the waters would be thus
abstracted, and as against the cost to the country might
be set the advantage of allowing anybody along the course
of the sewage channels to use the sewage if he thought fit
to do so under proper restrictions. There is an earnest
desire existing throughout the country to restore the rivers
to a wholesome condition—a desire shared by local
authorities as much as by landowners; but the object to
be attained must be subordinate to some other important
considerations. Manufacturers give employment to vast
numbers of men, women, and children, to whom the
highest purity of the streams would be comparatively of
little moment if their sources of occupation were gone;
the home manufacturer is exposed to keen competition
with his foreign rival, who can work his servants long
hours, and escape from a variety of restrictions to which
his British competitor is exposed. As regards town
sewage, distinguished from manufacturing pollutions, the
refuse must be got rid of somehow or other. It cannot
remain in the town; and the Government, when they
issued their commissions, were so fully sensible of this
that they laid down conditions, which must not be over-
looked by those who are seeking after purity, that by
whatever means the remedy is to be effected, that remedy
must be "without risk to the public health, or serious
injury to industrial processes and manufactures." These
conditions appear to have been lost sight of in the Lords'
bill, and notably so in the circumstance that no new
sewage outlet was to be made in a watercourse, or any
new use made of an old sewage outlet. This would
involve the retention in the town of sewage thus placed
under ban until a scheme of purification was devised and
executed, a state of things which would be past all
endurance. The feeling of the present moment seems to
run high in favour of sewage farming. Without disputing
for a moment the advantages of water as a medium of
transporting sewage, and without entering upon the
question of pecuniary results, the difficulties already
pointed out show that as to many places the sewage farm
is impracticable. To this observation must be added the
important general remark that, if 20 acres per soul be
about the proper scale for scientific sewage farming, it is
doubtful whether sufficient land exists, suitable in point
of level or otherwise, for the undertaking. Those who are
earnest in the matter, and are animated by a desire to
promote the public health in preference to the success of
any pet doctrine, should bear in mind the responsibilities
they incur in pressing forward impracticable measures.
Admitting the fitness of sewage farming properly conducted
for suitable places, there must remain enormous districts
in area and population where the liquid refuse must be
cleansed within a short distance of the outfall. To work
out this task effectually mechanical appliances are in-
dispensable; but it is to the chemist we must look for the
perfection of the undertaking, especially as enabling the
operation to be conducted inoffensively, so as to destroy
smell effectively, so as to speed consolidation of products,
so as to admit of removal profitably, so as to concentrate
the fertilising agents, and satisfactorily as to effluent
waters. And whilst provincial towns are being rightly

looked after by the Government, it should not excite surprise if they draw invidious comparisons between the zeal with which they are pursued and the indifference manifested in the metropolis, where a board enjoying almost unlimited taxing power is allowed to discharge the sewage of three million people into one river, under the very nose of Parliament, and in sight of those equity judges whose decrees are fulminated against the country towns, some of which judges, together with many puissant Lords and gentle Commoners, complacently drink their diluted London sewage whilst severely condemning similar impurity in water used only for business purposes in the provinces. If sewage farming on a large scale is the proper thing, we may fairly ask why the Board of Works has not carried the famous Essex reclamation scheme; or if precipitation or filtration be good, why they have not applied it around Abbey Mills, at Plumstead Marsh, with all the advantages incident to having the highest engineering, mechanical, chemical, legal, and scientific skill ready at command. The fact that no attempt is made by such a powerful authority under such favourable auspices to ascertain whether mere domestic sewage on a large scale can be successfully dealt with, so as to yield profit and avoid fouling streams, is an argument, not that other towns with infinitely great difficulties should go unchallenged, but that they should be treated with consideration; that rash indifference should be avoided; that due regard should be paid to manufacturing interests which are of national importance; and that, as attempted by the Aire and Calder Conservancy Bill, the Government should endeavour to promote amicable co-operation amongst the parties interested, in preference to legislating recklessly or harshly, or thrusting down the throats of honest people dogmas which, after enormous expenditure and infinite discomfort, may prove to be erroneous.

ZINCO-MAGNESIC CHLORIDE.

By GEORGE WARNER, F.C.S.

IN CHEMICAL NEWS, vol. xxvii., p. 271, I published a brief note on zinc-baric chloride, and at the same time stated that I had prepared zinc-magnesian chloride. It is prepared by dissolving magnesian chloride in a hot solution of zinc chloride to saturation. The solution of zinc chloride should be concentrated until of 1·6 sp. gr. before the addition of the magnesian salt, by this means avoiding the partial decomposition of the latter, which must ensue during the prolonged evaporation necessary to obtain the right degree of concentration for crystallisation. Upon cooling, a crystalline mass is obtained, which, when drained and re-crystallised, produces the double salt in rhombic prisms with truncated summits, of the composition $\text{ZnCl}_2, \text{MgCl}_2, 6\text{H}_2\text{O}$, or, in 100 parts—

	Found.	Theory.
ZnCl_2	40·29	40·15
MgCl_2	28·07	28·01
H_2O	31·64 by diff.	31·84
	100·00	100·00

This salt is extremely deliquescent, and, compared with other compounds as hygroscopic substances, was found to stand in regard to them as follows:—The figures represent the proportionate quantity of moisture absorbed from the air in a given time, calcic chloride which has been evaporated to dryness and ground taken as a standard.

Calcic chloride	1·00
Calcic chloride, cryst.	0·52
Zincic chloride, cryst.	1·00
Zinco-baric chloride, cryst.	0·40
Zinco-magnesian chloride, cryst.	0·59
Magnesian chloride	0·43

Ardwick Bridge Chemical Works,
Oct. 1, 1873.

NOTE ON THE LEAVES OF THE BEECH.

By J. ALFRED WANKLYN,

Corresponding Member of the Royal Bavarian Academy of Sciences.

IN the course of my experiments on different kinds of leaves regarded as material for making tea, I have observed a very interesting fact connected with the beech. Its leaves yield to boiling water 20·8 per cent of extract. This is reckoned on the absolutely dry leaf. The 20·8 parts of extract yield on incineration 2·44 parts of ash, and this ash, extraordinary to relate, is sensibly charged with manganese. Indeed it is quite green from the manganese which it contains. On being treated with water it gives the characteristic red solution of permanganate, which loses its colour on treatment with oxalic acid. The decoction of beech leaves, therefore, contains a quantity of manganese.

Another fact worth noting is the great fragrance of decoction of beech leaves; possibly it might be used as a beverage.

Returning to the chemical aspect of the subject, I cannot let slip this opportunity of recommending a study of the ash of leaves. It is quite to be expected that some of our common leaves may be found to be charged, not with potash, but with caesium or rubidium. That cigar-ash is laden with lithia is indeed known. Perhaps a diligent search into the ash of leaves may disclose new elements. Recent research has brought into prominence the selective power of plants which will refuse to draw soda from a soil that is charged with soda, but will select the traces of potash that it contains.

ON TEA.

By J. ALFRED WANKLYN.

THERE is no doubt that tea is sometimes adulterated with iron-filings and other preparations of iron, and when public analysts have found that iron had been put into tea leaves they have doubtless, in some instances, found that which really had taken place.

The ash of genuine tea leaves, however, contains iron, and by no means a small proportion of it. In a paper by Zöller (*Liebig's Annalen*, May, 1871), the percentage of oxide of iron in the ash of tea leaves is given as 4·38 per cent. The importance of this determination depends upon the circumstance of the tea having been received direct from the growers, who were personal friends of Liebig's; in that instance, therefore, there could be no question of adulteration. It may be interesting to reproduce Zöller's analysis, which is as follows:—

Potash	39·22
Soda	0·65
Magnesia	6·47
Lime	4·24
Oxide of iron	4·38
Protoxide of manganese	1·03
Phosphoric acid	14·55
Sulphuric acid	trace
Chlorine	0·81
Silica	4·35
Carbonic acid	24·30
	100·00

From this it is abundantly manifest that the mere qualitative detection of oxide of iron in the ash of tea is no valid proof of adulteration; and that in order to make out a case it is necessary to show sensibly more than 4 per cent of oxide of iron in the ash.

On the present occasion I wish to call the attention of public analysts to the importance of investigating the ash of samples of tea. Zöller found the ash of tea leaves to be 5·63 per cent, using in his investigation tea leaves of

guaranteed purity. I find that commercial tea yields a very similar result, as is seen from the following analysis made in my own laboratory:—

	Percentage of Ash.
Specimen of tea used by myself..	5.63
Civil Service tea	5.56
Horniman's tea	5.99
Mandarin's tea, 8s. per lb. ..	5.30
Orange Pekoe, 5s. per lb. ..	5.84
Do. do.	6.06
Green tea, 4s. 6d. per lb. ..	5.86

Average .. 5.75

These determinations were made on tea in its ordinary air-dried condition, and agree sufficiently with Zöller's. The proportion of ash in absolutely dry tea is 5.92 per cent.

Zöller further calls attention to the composition of the ash of spent tea leaves. This, as might be expected, is far less rich in alkalies, being far less soluble. Zöller's analysis is as follows:—

Potash	7.34
Soda	0.69
Magnesia	11.45
Lime	10.76
Oxide of iron	9.53
Peroxide of manganese ..	1.97
Chlorine	trace
Phosphoric acid	25.41
Sulphuric acid	trace
Silica	7.57
Carbonic acid	25.28

100.00

This ash, as a matter almost of course, must be composed mainly of material insoluble in water.

For practical purposes, that is to say for use by the public analysts, a complete analysis of the ash would be too cumbersome and troublesome. A great deal of information may, however, be gathered from a tolerably simple operation, viz., from a determination of the relative quantities of soluble and insoluble ash in tea leaves. With the object of rendering a determination of this sort available, I have made such determinations on dried leaves of various kinds. The leaves, with the exception of the tea and Paraguay tea leaves, were gathered by my assistant on the 24th of August this year. The following are the results:—

	Percentages on the Dried Leaves. The Ash.		
	Total.	Soluble in Water.	Insoluble in Water.
1. Common tea ..	5.92	3.55	2.37
2. Paraguay tea..	6.28	4.22	2.06
3. Beech	4.52	2.00	2.52
4. Bramble	4.53	1.84	2.69
5. Raspberry ..	7.84	1.72	6.12
6. Hawthorn ..	8.05	3.78	4.27
7. Willow	9.34	4.16	5.18
8. Plum	9.90	5.66	4.24
9. Elder	10.67	3.19	7.48
10. Gooseberry ..	13.50	7.83	5.67

From this table it will be apparent that the ash of Paraguay tea is the only ash capable of being mistaken for the ash of tea; the total percentage would of itself exclude all the others. The ash of Paraguay tea is, however, distinguished from the ash of common tea by containing a higher proportion of soluble matter.

The ash of beech and of bramble is distinguished from that of tea by being too small in amount, and by containing too little soluble matter. All the rest are exceedingly unlike tea ash.

The determinations of the total, the soluble, and the insoluble ash in leaves are made with great facility. Dried leaves burn up with great ease; and, for the purpose of getting a complete combustion there is no occasion for the

employment of nitric acid. I am in the habit of employing about 2 grms. of the dried leaves for the experiment. These I burn in a small platinum dish, and when the resulting ash has become grey, I allow the dish to cool and weigh it together with its contents. The ash is then heated to boiling with a little water, and the solution filtered, and the filtrate evaporated to dryness in a small platinum dish; the resulting residue is then ignited, cooled, and weighed. Thus I get determinations of "total ash" and "soluble ash"; the "insoluble ash" is found by difference.

Sand is sometimes found in tea leaves; this is very easy of detection. It will, of course, remain in the insoluble portion of the ash, and refuse to dissolve when that is treated with hydrochloric acid. The portion of real tea ash which is insoluble in water is almost entirely soluble in hydrochloric acid.

Very many uses may be made of a determination of the ash in a sample of tea. As an example of what may be learnt from such determinations, I will cite an imaginary case, which, however, finds its parallel in practice. Let us suppose that the tea yielded the normal proportion of ash, viz., 5.75 per cent on the air-dried leaves, and let us suppose that one-third of this consisted of sand. With these data before him the analyst would be justified in finding, not only that there was a little sand in the tea, but that at least one-third of the sample did not consist of genuine tea, but either of some other kind of leaf or of spent tea (which is not so rich in ash as genuine tea).

On a future occasion I hope to publish further researches on tea, and will conclude with an expression of my conviction that a little careful chemical work bestowed on the subject of tea will render the examination of it highly certain and satisfactory.

MEMORANDUM ON THE METALS AND MINERALS OF UPPER BURMAH.

By Captain G. A. STROVER, Political Agent, Mandalay.

THE Chief Commissioner having called for a report upon certain mineral products of this country, it has occurred to me that, as many years have elapsed since any concise information has been given upon the subject of metals and minerals generally, and as our knowledge regarding these products has been greatly extended of late in consequence of increased intercourse between the British and Burmese Governments and the subjects of each nation, it will not be out of place, and of some interest, to give a brief sketch of the resources of Upper Burmah as regards the same.

Gold.—It has been generally supposed that Upper Burmah is not rich in itself as regards this metal, but there would seem to be good grounds for supposing that it exists very extensively. In former years the gold used in the country was imported from China to the extent of some 400 or 500 viss annually, but the imports have considerably decreased since the commencement of the Mahomedan rebellion in Yunan, and now do not exceed 200 viss per annum, the deficiency being imported from Rangoon. It is an article largely used in the decorative art, and appears to be generally plentiful.

In the Mogoung district there would seem to be a gold-field that, if properly worked, would prove very productive. Some years ago, a Mr. Golding, of Australian experience, contracted with the King to work 1 square mile of this field for a sum of Rs. 25,000 annually for ten years, but unfortunately the district proved to be malarious, and Mr. Golding succumbed to fever; he, however, pronounced the fields to be equal to any in Australia, if not better. I am not aware that he succeeded in procuring much gold. Since then no attempt has been made on the part of the Burmese Government to work the mines.

To the north-east of Mandalay, in the Shan States, there is another field of gold. My information tends to show that here again, with energy and enterprise, con-

siderable quantities of gold could be extracted, and the mines prove very productive; but the locality at present is malarious, and but little gold is procured.

At Thayet-pein-yua, near the Myit-Nyay, on the road to Pyoungshoo, to the south-east of Mandalay, the gold quartz is found in abundance, the reefs cropping up from the ground, and there is reason to believe that very valuable gold mines are in existence, and could be worked and developed with little trouble. A Shan lately procured from here a piece of quartz $3\frac{1}{2}$ lbs. in weight that produced exactly 2½ ticals of gold.

In the Yaw district, to the south-west of Mandalay, gold is obtained in fair quantities in the alluvial deposits; it exists at Sagaing, Kannee, Sein-joo, and is also obtained from the Kyeend-ween river, and, indeed, it is procurable from the sands of most of the streams between Mandalay and Mogoung. The natural conclusion from this profusion of gold in the rivers and streams of Upper Burmah is that it exists in large quantities *in situ* somewhere, and, as I have explained, this is the case, and doubtless there are more deposits that have not been discovered.

Silver is found in many localities in the Shan States to the east of the Irrawaddy river, but the most prolific mines are those situated at Bawvine, Kyouktch, and Tounghbyne, near Theebaw, to the north-east of Mandalay. It is mixed with lead, and is in fact a rich argentiferous galena. One mine, the Kampanee, will yield as much as 40 ticals of silver and 25 viss of lead from one basket of the ore, while the poorest mine gives 4 ticals of silver and 30 viss of lead. Other mines exist, such as the Baudween, Baudweengyee, and Sagaing. The metal is also found in other towns unmixed with lead. The supply of silver obtained hitherto has been sufficient for the requirements of the country in conjunction with the imports from Yunnan.

Copper.—This metal is found in the Shan States, but is not worked. It is also found at Kolen-myo and Sagaing; at Bawvine and Kolen-myo the malachite appears to be of a rich description. The copper resources of the Shan States do not appear to have been ever utilised to any extent, and the deposits, which seem to be abundant, remain as Nature placed them. The Sagaing mines were worked in former times by Chinese, but many years have elapsed now since they were abandoned. The surface ore is not promising. Most of the copper used in Upper Burmah is imported from China. It is plentiful in the province of Yunnan.

Iron.—Iron abounds in the Shan States, and the district of Pagan, to the south of Mandalay, is noted for it. A manufactory exists on a rough-and-ready scale in this district at Pobpah Toungh, but the out-turn is inconsiderable. To the west of Sagaing, for miles up the Irrawaddy river, the ore abounds—a rich hematite. His Majesty is now procuring iron-works from England, and will before long have a large foundry, with all the requisite machinery, erected and at work at Sagaing. The surface hematite alone will feed it for years to come, if worked. Two mining engineers are now awaiting the arrival of the works, and expect to proceed to Sagaing soon to commence operations.

Lead is found in abundance in the Shan States, and is extracted from galena. Considerable quantities of this metal could be obtained if such was desired. At present moderate supplies are procured, sufficient for the requirements of the land. It is also imported from Yunnan.

Tin.—This metal exists in the Shan States to the south-east of Mandalay, but the mines have never been worked. The tin consumed in the country now is all imported.

Platinum is said to exist in the Shan States, and it seems probable that it does exist, but I have no reliable information on this point.

Graphite is found to the east of Nat-taik in large quantities on a low range of hills near the village Nyoke-toke. It is not utilised.

Coal.—This mineral is known to exist at Thingadaw, about 70 miles above Mandalay, on the western bank of the Irrawaddy; at Shuaygoo below Bhamo; at Meim-

baloung in the Shan States east of Mandalay; to the south-west of Mandalay in the Yaw district, at Yaignaw, east of Nat-taik. It is found at Pagan and Shimpagah, and it is probable that it exists near Meuhla and Yeynang-young. At Thingadaw the coal has been extracted, but it is of an inferior description, and more resembles lignite than the true mineral coal. An attempt was lately made here to ascertain the productiveness of the coal-beds. It is nearly certain that plenty of coal exists in the locality, and a few more borings would probably prove this. The coal-bed in the Shan States at Meimbaloung contains the true mineral coal, and consequently a valuable coal. It has been inspected by an experienced mining engineer, and highly approved of as equal to the best English coal. There is little doubt that the beds are extensive, but unfortunately the distance in land is great, and no easy means are available for transporting the coal to the low lands; indeed, the only method at present is by floating it down mountain-streams and rapids on rafts, which entails considerable risk and loss of coal. European skill and enterprise would soon make a safe route of one description or another if really required by the Government; it remains at present, with neighbouring wealth, where Nature placed it, awaiting development at times to come.

Jade and Amber.—The quality and extent of these mines above Mogoung is well known. They are both extensive and capable of development.

Sulphur.—This substance is not found in mass or in its native state in Upper Burmah, *sui generis*, but is found in efflorescent salts, and is manufactured from metallic sulphurets. The following is a list of localities where it is made, and the yearly average out-turn:—

	Viss.
Mooda Myo, N.	3000
Tsein-noon, E.S.E.	2000
Kyouk-hoo, S.E.	3000
Bawvine, Shan States, S.E.	6000
Dybayen Myo, N.W.	4000
Pagan Myo, west bank of the Irrawaddy	4000
Toungthoo Einlay, E.S.E.	4000
From the Bhamo district	2000

Total viss yearly 28,000

At Toungthoo Einlay, to the south-east of Mandalay, sulphur is manufactured by the Toungthoo Shans, who sell their out-turn to the King; at all the other places the mines are worked by His Majesty.

The Bawvine works have been increased during the past month by four extra furnaces, which will give about 5000 viss more per annum. The sulphur ore appears to abound in the Shan States; in fact, at Bawvine, Kyouktah, Dybayen, Pagan, and Toungthoo Einlay, the supply seems to be unlimited. It is found in the tertiary blue clay from 12 to 20 feet below the surface, which is an alluvial deposit of the old red sandstone; it is embedded in the clay, and consists of very hard metallic pyrites of some size.

The mode of extracting the sulphur is very simple. The sketch below illustrates it:—

Common chatty-shaped vessels are made on the spot from the soft blue clay in which the ore is found. The larger vessel is filled with broken ore, and placed on a fire, a clay retort being fitted to the top, and communicating

with the smaller vessel. The sulphur is thus sublimed and condensed as shown, after which the retort is broken, and a hollow tube of flower of sulphur extracted therefrom which is superior to that condensed in the vessel. Iron pyrites do not appear to be utilised in the manufacture of sulphur, and it is doubtful whether the Burmese could utilise them. These pyrites are to be found in abundance in parts of Upper Burmah and the Shan States. The imports from Yunnan are also considerable every year.

It is manufactured in Yunnan, and in the "Shit-Pyee-Doung," or eight Shan States to the north-east of Bhamo, at present under the rule of the Chinese, or tantamount to the same. European sulphur can be purchased in the bazars at the rate of Rs. 3 per viss.

Saltpetre is manufactured at the following places in Upper Burmah:—

- | | |
|-----------------------|--------------------------------------|
| 1. Tounghthoo Einlay. | 14. Yoon-doo. |
| 2. Ameerapoor. | 15. Myo-tha. |
| 3. Shimpagah. | 16. Tsit-kine. |
| 4. Ong-ben-lay. | 17. Alon. |
| 5. Leen-gine. | 18. Tee-ber-Yeen. |
| 6. Sameet-koon. | 19. Myay-Yeen. |
| 7. Pyogan. | 20. Shin-bin-oon-Eni. |
| 8. Aung-gyeen. | 21. Yua-shit-gyee. |
| 9. Samoon-gyee. | 22. Enidyne Yuo (Kyousay, S.E.). |
| 10. Oo-yun-galay. | 23. East of Pagan (Yoongdaw Toungh). |
| 11. Shuaybo. | |
| 12. Satoung-ma. | |
| 13. Salem-myo. | |

The yearly average out-turn is about 40,000 viss. The manufacture is not prohibited as with sulphur, and considerable quantities are used in the preparation of fireworks.

The manufactures at Tounghthoo Einlay, Eindyne, Kyousay, Yoongdaw Toungh, and Sameet-koon can produce very largely if required.

At Tounghthoo Einlay the Tounghthoo Shans in former times used to make from 20,000 to 25,000 viss of saltpetre per annum, but emigration to British territory has considerably reduced this.

The price of saltpetre is Rs. 50 per 100 viss. Many parts of Upper Burmah are well suited for its manufacture, the ground being well supplied with nitre.

Rubies, Sapphires, Garnets, &c.—These are found in abundance at Mogouk, Kyat-pyee, to the north-east of Mandalay near Momeit. The ruby ground extends over a large area of hilly country. The gem sand is found from 3 to 15 feet below the surface soil, and the beds are then followed up. The method of working is primitive and rough, the consequence being that large rubies are seldom extracted intact.

Some years ago, a Mr. Bredamajee, a German mineralogist, was located at these mines for the purpose of developing them, but, after a short stay, he got into trouble with the people, and was dismissed.

He declared that, with careful working, rubies as large as pigeon's eggs could be extracted, and that the mines were very rich. At Mogoung, also, ruby mines exist, and very fair rubies have been found. The Sagyeen or marble hills, a short distance to the north of Mandalay, contain the gems as well, but they are of too light a colour to be valuable; they are, however, mixed with other rubies and disposed of.

Salt.—Extensive salt-fields exist at Shimpagah, a short distance above Mandalay, on the western bank of the Irrawaddy river. It is also obtained at other places in Upper Burmah on a small scale. Large quantities can be manufactured at Shimpagah, but imported salt is fast taking its place in the market. The hill people, though, appreciate to a certain extent the Shimpagah salt, and mix it with European salt.

Petroleum.—This mineral oil is found at Yegnanangyoung and Pagan, but information regarding it is so complete that it is hardly necessary to allude to it further. I will, however, make a few brief remarks. There are at present

about 150 wells worked at Yegnanangyoung; the quantity of oil estimated as deliverable from these wells is 15,000 viss daily, of which 10,000 viss is taken by the contractor who supplies British Burmah, and 5000 viss by the contractor who supplies Upper Burmah. The total yield of these wells is 6,000,000 viss per annum, or 9375 tons. There are many abandoned wells, and wells that produce very small quantities of oil. At Pagan there are about 50 wells; they yield daily 1500 viss of oil, which the earth-oil contractors, at present the Lay-myo-woon and one Moung Tsanwah, are allowed to purchase. The oil from these wells is obtained in a more liquid state, and more resembles naphtha. It is of a brackish nature, and is better suited for lighting purposes than the Yegnanangyoung oil. The total supply of earth-oil in Upper Burmah now per annum is 6,600,000 viss, or 10,312½ tons.

I have omitted to mention marble and limestone, but both abound.

Upper Burmah, with its metals and minerals, its forests, natural resources, productiveness of soil, and from its geographical position, situated as it is close to the teeming population of the Chinese empire, ought to be the richest country in Asia, and Rangoon one of the largest emporiums of trade. The productiveness of the soil, as regards cereals and other crops, is wonderful. The indigo plant, which is prolific in its growth, gives three crops per annum, and the dye would quite equal that of Bengal with careful and proper treatment in its manufacture. Paddy, wheat, cotton, cutch, grain, sesamum, sugar-cane, tobacco, tea, coffee, each has its own soil in abundance.

Teak and other useful trees abound, and, taking all in all, Upper Burmah would seem to have a grand future in store for it, as civilisation advances and old prejudices give way to new and enlightened ideas.

A few remarks on india-rubber or caoutchouc may be of some interest.

The estimated number of trees, which are chiefly situated in the Bhamo and Mogoung districts, is 400,000. They thrive best in damp moist soil, and in thick forests, shady and cool. The trees attain to a height of from 50 to 100 cubits, being from 15 to 20 cubits in girth at the base (full-grown trees), and with roots creeping over the ground for some distance. They are fit for tapping when from six to ten years of age, at which time they are from 15 to 20 cubits in height and 3 cubits in girth.

When the time for tapping arrives, incisions are made in the trunks of the trees and in the roots above ground. Hollow bamboo cups, about 1½ feet in length, sloped and pointed similar to a prepared pen, are then inserted in the incisions, and receive the oozing juice or milk. Three- or four-hundred of these bamboo receptacles are inserted in each tree. The tapping is continued for about a month, after which time it is discontinued, and the wounds allowed to heal. At the expiration of another month the trees have regained strength, and tapping is recommenced.

In preparing the india-rubber, the following crude method is observed:—Water is boiled in large iron pans, and the juice of the tree is thrown in, when it gradually thickens, and subsequently is dried. The india-rubber so obtained is being brought into local use for covering water-buckets, baskets, and boxes as a substitute for dammer.

The existence of the india-rubber tree in Upper Burmah does not appear to have been known, or, at any rate, it did not attract attention, until somewhat recently, when three Europeans, Messrs. Miller, Marshall, and Henri, who were employed at the jade stone mines, were forced to look and search about in the forests for a substance that would effectually repair a diving apparatus that they used in working for jade stone. They found india-rubber, and repaired the apparatus. The existence and value of the juice was then brought to the notice of the King, and Mr. Henri is now employed in tapping the trees and preparing the juice. Some 70,000 viss of india-rubber was brought from Mogoung last year. I myself saw thirty or

forty cart-loads of it entering the palace one day. Upper Burmah could produce 200 or 300 tons of this useful substance per annum.

January 22, 1873.

ON THE ENERGIES OF THE IMPONDERABLES, WITH ESPECIAL REFERENCE TO THE MEASUREMENT AND UTILISATION OF THEM.*

By the Rev. ARTHUR RIGG, M.A.

(Continued from page 178).

THERE are other substances on which this same law, determining the rate at which the affinities are to operate, may be impressed. Gun-cotton is one. We are again obliged to Mr. Abel for two illustrations on the wall showing the destruction of the martello tower at Dimchurch, in Sussex. It was accomplished with 186 lbs. of compressed gun-cotton. And the development of the affinities was such that the tower changed at once into the form you see in the second diagram. Had gun-cotton in the same state of combination and of the same character been put into a cannon, in all probability the cannon would have burst before the ball had time to move.

Some very peculiar and inexplicable affinities are presented by this ally or rival of gunpowder, viz., gun-cotton. In the first place, the rate of combustion and the consequences of it may be previously regulated, and that with much accuracy. Its energy may be mild or great, at the will of the operator. The results of numerous experiments is, that to obtain the full power of gun-cotton it must be exploded in a close chamber, in order that the gases and heat generated by the first part of the explosion may penetrate the mass. The records of experiments with gun-cotton show very plainly the absolute necessity for considering how affinities comport themselves. A bag of gunpowder nailed on the gates of a city would blow them open; a bag of gun-cotton so nailed would fail. Put the gun-cotton in a box, and it will shatter the gate to atoms. A box of gun-cotton flung down close to palisades would open a passage for troops.

Spectrum analysis reveals the fact that the spectrum from the flame of a compound body, as chloride of calcium, is not the same as that observed in the electric spark passing over pieces of chloride of calcium. The explanation suggested is that certain chemical compounds, when they are heated above a given temperature, are decomposed into their constituent elements below that temperature. These compounds are capable of existing in a permanent state. It may be thus with the energy of gun-cotton. When discharged at the temperature of flame, the gaseous constituent elements are not formed, and therefore no explosion. When at the higher temperature producing concussion, then the constituents are formed, and explosion ensues.

You will find that the rate at which gun-cotton explodes depends upon the rate at which the affinities are called into play. Here is a specimen. If we bring the affinities of this gun-cotton into play by means of a spark, and thereby do not produce sufficient heat to develop its affinities rapidly, the rate at which the gun-cotton is consumed is comparatively slow. If we bring its affinities into a flame, the rate at which affinities are developed in consequence of the heat is great. If we bring them into play by means of detonation, the rate at which they are developed is greater still. You see that when a flame is applied to this strip of gun-cotton it runs along it rapidly, whereas when a spark is applied to a piece of the same material the combustion is slow, like touch-paper. If I hold up the string of spark-ignited gun-cotton, the heat gathers, the ignition becomes more rapid, the spark being converted into a flame. Now if instead of allowing the

affinities to be exercised at that slow rate we cause them to develop immediately, we should have had a very different result. Here is some pulp gun-cotton, the very form in which it was used for the destruction of this tower. If we detonated some of that, we should none of us be here to tell the tale of how it went off. There is enough in my hand to send the walls of this room in all directions, but it must be by detonation. The effect of what is something like detonation can be shown in a different form. You are aware that in a coal-mine there are fearful explosions. It has been found that these explosions often take place after a blast in a distant part of the mine. The question therefore is, what has that blast to do with the explosion, the two not being near together? Mr. Galloway, of the Meteorological Office, has been investigating this matter for some time past, and it has been found that these Davy safety-lamps, of which specimens are on the table, are not, when within the influence of a reverberation of the air from the effects of a blast in a distant part of the mine, always as safe as they are supposed to be.

The lamp consists of a flame within gauze; and when surrounded by an explosive compound, owing to the inability of the flame to penetrate the gauze, the explosive gas does not ignite. If, however, detonation takes place, even at a distance from the lamp, then we shall produce those conditions which are favourable to the development of chemical affinity. Here is a Davy safety-lamp, lighted, and now placed in an atmosphere of explosive gas. The question is, what will happen in case a shot is fired in a distant part of the mine? In the case before you the lamp is placed at one end of a long tube, the other end of which is closed by a piece of india-rubber, and in continuation of, but detached from, the long tube there is a short tube of the same diameter. There is no communication whatever between the two tubes, and, as you may notice, there is a space between the ends of them. My intention is to fire a pistol at the open end of the short tube; the explosion will cause the india-rubber to be compressed, and so to act on the air in the longer tube. You probably know that if there were on the table a box with an elastic back, and a candle at the other end of the room, opposite to a hole in the front of the box, then by striking the box at the back the candle would be blown out. Now, on firing the pistol, having its end in this short tube, the india-rubber is compressed, and the gas surrounding the Davy lamp, which is supposed to be in a distant part of the mine, at once bursts into flame. This is the same phenomenon that takes place when shots are fired in one part of a mine, and an explosion occurs in another part.

This is all well and good if it would help towards a solution of the question of regulation of the energies of these affinities, if only we could delay the affinities as we delay them in gunpowder, because we might then do what Galileo did when he delayed the ball down an inclined plane; or what Kater did when he caused the pendulum to repeat itself frequently, and so record the effects of gravity; or what Atwood did when he took a small weight and caused that to fall by gravity, but distributed its effect through a large mass. The consequence was that they were enabled to observe what the law of gravity is. If, now, we could rely upon such a process of delaying the affinities as has now been mentioned, we should then have a chance of ascertaining their energies; but we cannot rely upon it, for two reasons. In the first place, there are a number of phenomena classed under the head of nascent actions, which constantly interfere. Let me explain what that is. At the time that certain substances are being formed, certain affinities exist which do not exist afterwards. If, for example, you manufacture hydrogen and then bring nitrogen, from another process of manufacture, into contact, they do not combine. If, however, you manufacture them both in the same vessel, they combine and form ammonia; and hence, in the case of putrefying vegetables, there arises that peculiar

* The Cantor Lectures, delivered before the Society of Arts.

ammoniacal smell. Here is some permanganate of potash, which, when dropped into this tube of coloured liquid, will produce certain phenomena, which take place owing to this nascent action—the colour will be discharged.

Then there are another set of actions which are more peculiar still, which manifest great energy, but which actions interfere with our measuring the energy of affinity as utilised by men. We have here a piece of platinum, and here is an argand burner, connected by a flexible tube with the gas-pipes of the room. Over the argand burner is placed this copper cylinder on three legs, having a wire gauze top. The sheet platinum is now coiled and placed on its edge on the gauze. The tap is opened, and the gas now burns with a lambent blue flame. Observe, the platinum is now being heated; now it glows. Let the gas be turned off. The flame is now extinguished; the once glowing platinum has become black. Thus far is nothing peculiar. Again, the gas is turned on. The black platinum is passing to a dull red; now it glows again, but the gas is not ignited, and the platinum remains at this red-white heat without any apparent cause. If a glass cylinder, to protect it from currents of air, be placed round it, this apparent burning without being consumed will continue during the remainder of the lecture, and, were conjuring tricks an object, it might be said that light and heat were here produced without the destruction of any materials. This is a case of what is called catalytic action. Phenomena like these perplex very much in estimating the energy of affinities.

Here is another case, of a like peculiar character. This is a coil of platinum wire, and you will find that if made red-hot, and then placed in a vessel of ammonia, although there is no gas in it, the platinum continues red-hot. There is no reason, apparently, why it should continue in that red-hot state.

(To be continued.)

CORRESPONDENCE.

THE LATE MR. CHAPMAN.

To the Editor of the Chemical News.

SIR,—That the splendid chemical work with which the late Mr. Chapman has enriched science was carried out in the laboratory over which I presided is almost as well known as the work itself, and most chemists will be surprised to read a biography of that distinguished chemist which describes his having been at school in Heidelberg and attended the lectures of Bunsen and Delffs, and his having studied in the laboratories of Hofmann, Frankland, and Kolbe, but omits all mention of his ever having worked in my own laboratory. Such a biographical curiosity, which may be seen in the last number of the *Journal* issued by the Chemical Society, affords an apt illustration of the real objects which are aimed at by the official body in charge of the Society, and is a worthy sequel to the refusal of the Society to publish one of Mr. Chapman's best pieces of work.—I am, &c.,

J. ALFRED WANKLYN.

Oct. 2, 1873.

MISCELLANEOUS.

Analysis of Milk.—A work by Mr. J. Alfred Wanklyn is in the press, entitled "Milk-Analysis;" it will, we understand, be published in a few days.

Society for the Promotion of Scientific Industry.—In a former number of the *CHEMICAL NEWS* was advocated the establishment of a Society of Manufacturing Chemists. But the manufacturers and promoters of scientific industry of Manchester have gone beyond the

proposed limits, and have established the Society whose title heads this paragraph; they have not confined themselves to the science of chemistry alone, but extend help and assistance to all. The Society is in its earlier stages, but its success would seem to be certain. Founded on the principles of the celebrated Société Industrielle de Mulhouse, its object is the increase of the technical knowledge and skill of those engaged in the various industries; the improvement and advancement of manufactures and the industrial arts and sciences; and the general progress, extension, and well-being of industry and trade. This multiple object the Society seeks to attain by the encouragement of investigations and experimental researches in science and the arts, having a practical bearing upon industry; by the offer of premiums and rewards for the invention of new or the improvement of existing processes or products, and for the discovery of new raw materials, and for their application and use; by the reading and discussion of papers and essays of practical interest affecting industry; by the publication and circulation of such papers and essays, with the discussions upon them; by the formation of a library and museum of industry; by the holding of exhibitions; by having agents at the several seats of foreign industry, specially charged to report on all matters appertaining to the work of the Society; and by delivery of a course of technical lectures. The first series of these lectures will be upon the great staple industry of cotton. Amongst the papers to be read and discussed in the ensuing session, the first are:—"On the Economy of Fuel," by T. Prideaux, Esq.; "The Manufacture of Sulphuric Acid," by Frank Spence, Esq.; "The Law and Practice relating to the Protection of Inventions, with some observations upon the Patent Office Museum," by W. Lloyd Wise, Esq.; "The Mechanical Appliances used in Calico Printing," by W. Mather. The work done by the Society includes the sending out of thirty skilled workmen to Vienna to report upon the various great industries shown in the International Exhibition; the arrangements for forthcoming exhibitions in "textile fabrics" and in "fuel economisers." The Society is proposed to be supported by subscriptions and donations. The first year's subscription for a fellowship of the Society is three guineas, one-third of which will be funded; the second and subsequent years' subscriptions will be limited to two guineas. Manchester has the credit of the first step in such an important movement amongst scientific industries. Of the result, it was predicted in our former article that benefit, more or less, must ensue. From such principles, carried out with so much energy and vigour, the most brilliant prospects are a necessary sequence. There are certain subjects of human knowledge and enterprise whose difficulties always succumb to well-directed energy, and scientific industry has hitherto appeared no exception. The volume of Artizans' Reports upon the Vienna Exhibition, published by the Society for the Promotion of Scientific Industry, Manchester, will be published about the 20th of this month. There are thirty-six reports, which are said to be of a very high-class character.

NOTES AND QUERIES.

Gilding.—Will any of your readers tell me how to remove a firm black coating from the surface of gilt on cast copper? A year ago I fixed a cast copper ornament, heavily gilded, out of doors in a clear country atmosphere, and, though ordered to be, and supplied as, weather-proof, it turned colour after first fall of snow, and in three months was black, with what appears to me to have risen through the gilding. It sticks close, and rubbing with cloth and spirits of wine scarcely affects it. Can it be removed by any solvent without affecting the gold, and, if removed, is the same "blackening" liable to recur?—STAR.

Notes on the Utilisation of Sewage.—(From the "Report of the Main Drainage Committee for 1864," vol. 487.)

827. (To Mr. Hope.) Then the cost of that has to be added to the 6s. referred to, has it not?—Quite so. Professor Way, in his evidence before the Select Committee of the House of Lords on Town Sewage, put it very clearly, I think, in his answer to question 744. He says: "If you gave me dried sewage, it would be capital manure to any crops, no matter whether wheat or green crops, or grass; it is merely the

form in which you present it that makes it unsuitable for some crops. It strikes me that it is the same kind of thing as if a man were to owe me the value of an ounce of gold, and were to bring it to me in the shape of gold quartz, saying: "Here is so much gold quartz, which contains $\frac{1}{4}$ 15s. worth of gold; or whatever it may be. That would not be paying me at all; I should have to take it with all its disadvantages, and to get it out of the quartz."

1075. (To the same.) Would it be very costly to pump the sewage up into some reservoir on a height, so as to allow it to gravitate all over the country?—No, that is not a costly operation; Cornish engines can be employed, and are employed, to lift enormous quantities of water at very little cost.

1077. (To the same.) Have you made any calculations as to what the cost of the pumping would be?—No, I have not; but I know it is the fact that enormous quantities of water can be pumped to a great height at an almost incredibly small cost.

1118. (To Mr. Moore.) What amount of horse-power do you imagine that the Metropolitan Board of Works would have to use in order to lift the 80,000,000 gallons of sewage 200 feet during the ten working hours of the day?—I have made that calculation, but I have it not with me.

1119. (To the same.) How would you make that calculation?—One horse-power is equal to 33,000 lbs. lifted a foot in a certain time; that is the mode of calculation.

1120. (To the same.) That would be upwards of 8000 horse-power net, would it not?—I suppose it would require that.

1121. (To the same.) And it would be about 15,454½ gross horse-power?—I do not think it would require that for the height.

1122. (To the same.) If it is 8242½ horse-power net, how much gross horse-power would it be?—That would depend upon the difference for friction.

1127. (To the same.) You offer the Board of Works a farthing a ton for the sewage, do you not?—Yes, which they would raise with a power equal to 200 feet.

1128. (To the same.) And do you estimate that 136,000 annually?—The half of that would be a profit to them, because it would not cost them one-eighth of a penny per ton to lift it.

1136. (To the same.) How much of the sewage would cultivated land take?—That would depend on the state that the land was in. A market gardener at present manures at the rate of £20 an acre with solid manure.

1137. (To the same.) And you propose to deliver the sewage at a certain price to him?—Yes.

1138. (To the same.) Do you fix any price as the basis of your calculation?—The price to the whole of the consumers is a penny per ton. I do not think that it would answer any farmer's purpose to pay more than that.

1139. (To the same.) How many tons to an acre would you put on irrigated land?—From 4000 to 5000 an acre; that would be about £20 an acre.

1174. (To Mr. Smith.) And what would be the working expenses of your system, pumping, and so forth?—The sewage proper would cost about 1-12th of a penny per ton of sewage; that is, for coals, labour, and oil, exclusive of the plant.

1310. (To Sir Charles Fox.) Do you propose to pump by steam?—Yes.

1311. (To the same.) What would be the horse-power that you would require?—3,500 nominal horse-power.

1312. (To the same.) Do you assume the sewage to be 80,000,000 gallons daily?—Yes.

PATENTS.

ABRIDGMENTS OF PROVISIONAL AND COMPLETE SPECIFICATIONS.

Improvements in apparatus used in the manufacture of salt. J. Bowden, accountant, St. Mary's Road, Canonbury. February 3, 1873.—No. 399. The features of novelty of this invention consist—First, in arranging the heat flues of salt-pans in a zigzag winding or circuitous direction, instead of the said flues passing direct from the fires to the chimney as heretofore generally practised, and by these means to utilise the heat that is now lost, and thereby economise the consumption of fuel; secondly, in surrounding salt-pans with some substance or material which is a non-conductor of heat to prevent loss of heat by radiation, also in adapting a cover to the pan to protect it from rain or cold air; thirdly, the formation of a brine-tank immediately above the salt-pan through which the flues in a series of tubes or passages shall pass; the said tubes or passages coming immediately in contact with the brine in the tank will impart to it its heat, and thus increase the temperature of the brine.

Improvements in the manufacture of tin-foil, and in the covering of other metals with tin, also in the machinery or apparatus employed therein. J. H. Johnson, 47, Lincoln's Inn Fields, Middlesex. (A communication from Jean Baptiste Ferdinand Masson, Paris.) February 3, 1873.—No. 406. This invention relates to a peculiar process of and apparatus for manufacturing at one and the same time and in one apparatus, two sheets of tin-foil of any desired thickness, or of coating, if desired, a plate or sheet of lead or other metal with tin by allowing the molten tin to adhere to the sides of a prepared surface which is drawn up vertically through the bath of tin, being divided for that purpose. If a sheet of scoured metal be so drawn up, the tin will adhere permanently thereto and thus coat it.

Improvements in extracting animal grease and other impurities from wool. T. W. Dunn and O. Frangely, both of Trowbridge, Wilts. February 5, 1873.—No. 420.—Wool in its raw state is placed into a chamber into which steam is admitted, and is then pressed.

Improvements in the treatment and use of air for the manufacture of gas for lighting and heating purposes, and in the apparatus employed therein. C. W. Harrison, High Holborn, Middlesex. February 5, 1873.—No. 435. This specification describes a method of oxygenising air by passing it under pressure or otherwise through water or any other suitable liquid that will absorb a larger proportion of the oxygen of the air than of the nitrogen. The air thus oxygenised is recovered from the water by a pump or other suitable means and stored for use in a holder, whence it is conveyed by pipes to where required for use, and is then passed through a suitable hydrocarbon, and thus converted into inflammable gas or vapour adapted to lighting and heating purposes.

Improvements in the manufacture of explosive compounds, and in the apparatus used in such manufacture. S. J. Mackie, 3, Delahay Street, Great George Street, Westminster. February 6, 1873.—No. 445. This provisional specification describes apparatus for steeping cotton-pulp or waste in an acid bath, placing it in digesting pots, and removing the pots in a cradle by a crane to the cooling pond. Freeing gun-cotton from acid by passing it through rollers. Apparatus for ascertaining the amount of dry gun-cotton in a mass of wet material. Apparatus for granulating compound of cotton gunpowder. Apparatus for giving any desired density to granules of cotton gunpowder.

KING'S COLLEGE EVENING LECTURES.

CHEMISTRY.—MR. W. N. HARTLEY.

Monday and Thursday, 7 till 9 o'clock. For the course ending in March, £1 11s. 6d.

CHEMICAL ANALYSIS.—MR. W. N. HARTLEY.

Tuesdays, from 7 till 9 o'clock. Fee, £2 2s.

Two Courses of Lectures on Geological MINERALOGY will be given at KING'S COLLEGE, LONDON, by Professor TENNANT, to which the public are admitted on paying the College fees. One Course is given on Wednesday and Friday mornings, from 9 to 10 o'clock, commencing Wednesday, October 8th, and terminating at Easter, 1874. The other Course is given on Thursday evenings, from 8 to 9, commencing October 9th. The Lectures are illustrated by a very extensive collection of specimens.

Practical Instruction in Mineralogy and Geology is given by Prof. TENNANT, F.G.S., at his residence, 149, Strand, W.C.

Analysis of Food, Water, and Air.—MR. WANKLYN has opened a Laboratory at 117, Charlotte Street, Fitzroy Square, and is prepared to give Practical Instruction in Chemical Analysis to Medical Officers of Health, and to persons proposing to undertake the duties of Public Analysts under the new Act.

MR. C. ESTCOURT, F.C.S., ANALYTICAL AND CONSULTING CHEMIST.

Commercial Analyses of all kinds performed.

BOROUGH LABORATORY,
8, St. James's Square, John Dalton Street,
MANCHESTER.

PRACTICAL CHEMISTRY.

Laboratory, 60, Gower Street, Bedford Square, W.C.

Mr. Henry Matthews, F.C.S., is prepared to give instruction in all branches of PRACTICAL CHEMISTRY, particularly in its application to MEDICINE, AGRICULTURE, and COMMERCE.

The Laboratory is open daily, except Saturday, from ten to five o'clock; on Saturday, from ten till one o'clock.

Mr. Matthews is also prepared to undertake ANALYSES of every description.

For Particulars and Prospectuses, apply to Mr. Henry Matthews the Laboratory, 60, Gower Street, Bedford Square, W.C.

SUPPLEMENT TO THE CHEMICAL NEWS.

VOL. XXVIII. No. 724.

NOTICES OF BOOKS.

Quantitative Chemical Analysis. By T. E. THORPE, Ph.D., F.R.S.E., Professor of Chemistry, Andersonian Institution, Glasgow. London: Longmans, Green, and Co.

We have had occasion to notice the increasing supply of elementary chemical works which have latterly been issued in the British Islands. It may be—as we should be glad to find—that this increase is due to an augmented demand for chemical knowledge; that our delightful science is more and more forming a constituent part of a liberal education, and that those who devote themselves to chemistry as a profession are increasing in number and in public appreciation. Or it may, perhaps, be due to the fact that a smattering of science is fashionable, as it was in the days of Charles II.

The work before us is, however, if fairly used, not calculated to further the production of that very objectionable animal—the smatterer. Thoroughness has evidently been the author's object, and he has been far from unsuccessful in its attainment. If we turn to any of the examples we find the method of procedure clearly and fully described, the needful precautions indicated, and the possibility of failure as far as practicable cut off.

The author uses the most modern nomenclature, and it may be that his work, arranged as it professes to be for the use of artisans, will contribute something to familiarise practical men with this system. At present the "capriciousness of chemical terminology" is not without reason felt to be a grievance of no small magnitude. The question is very generally asked whether the benefits derived from the new nomenclature do more than counterbalance the confusion it has occasioned, and the additional difficulties in the acquisition of chemical knowledge which it has created.

The student who has carefully worked through the examples given in this volume, attending strictly to the instructions given, will be on the high road to becoming an expert and accurate analyst.

The subject of water analysis—no unimportant one in these days of rivers' pollution investigations, and mythological "previous sewage contamination"—is treated, as the preface announces, in considerable detail. We cannot help questioning the policy of attempting to instruct artisans in a process which chemists of the highest standing have after careful trial abandoned as fallacious, because—setting for the moment all other objections aside—the amount to be determined falls within the limits of error of a carefully and skilfully conducted combustion.

In conclusion, we can only pronounce this work a valuable addition to English chemical literature, and congratulate the Andersonian Institution on the style of instruction which evidently prevails in its laboratory.

Sewage: Suggestions for its Utilisation, having special regard to Sanitary Requirements. London: E. and F. Spon.

No better proof can be given of the difficulties besetting the utilisation of sewage than the number of treatises and pamphlets in which the question is discussed. Each author thinks that he has come upon the one essential point which all his predecessors have overlooked. Unfortunately the problem has not been examined with the

calm impartiality befitting men of science grappling with a great national evil. There has arisen an *odium cloacinum* even more rancorous than the well-known *odium theologicum*. The plainest facts have been overlooked or distorted; the strangest inferences drawn; and "recommendations" the wildest and most impracticable have been issued on high authority.

The recent outbreak of typhoid fever in Marylebone has called general attention to a source of danger suspected, indeed, long ago by a few judicious men, but disregarded by the press, the public, and by officialism. Let it be granted that cholera, fever, or other zymotic disease exists in a certain town. The germs of such disease must evidently find their way into the sewers; here they will not, under ordinary circumstances, meet with any agency capable of effecting their destruction. If, now, the sewage is applied, *untreated*, to the land, as in ordinary irrigation farms, these germs must be diffused over the fields. They may adhere to the surfaces of plants, and perhaps may even be absorbed into their capillary vessels. In either case there is no natural process at work by which their vitality is likely to be extinguished. They may thus be taken directly into the human system along with vegetables and fruits that are eaten uncooked; or they may be swallowed by cattle along with turnips, cabbages, Italian rye-grass, &c. Here, again, in the bodies of the cattle they are not, to the best of our knowledge, liable to be destroyed. According to certain recent researches, living *bacteria* are found in milk as it issues from the udders of female animals, and determine therein the formation of a small amount of alcohol. Such being the case, there is no *a priori* absurdity in the hypothesis that the milk of cattle which have drunk water contaminated with cess-pool matters, or, still more, which have been fed on herbage grown on a sewage-farm, may convey the germs of disease into the systems of human beings. This, it must be remembered, is not one of the cases where the benefit of a doubt can be given to the defendant. If a ship arrives from a port where pestilence is raging, the crew and passengers are placed in quarantine, not because they *have*, but because they *may have* about them the germs of the infection. Letters have appeared, indeed, asserting that in such and such quarters the milk from a sewage farm has not occasioned fever. This reminds us of the thief who, when confronted with several witnesses that had seen him stealing a horse, offered to produce as many more who had not seen him. We could lay our finger on certain districts in the eastern counties especially, where the inhabitants derive their supply of water for domestic consumption from road-ditches and duck-ponds, into which the drainage of richly-manured fields and of farm-yards fall, and which stand in indisputable connection with half the cess-pools in the village. Yet in these localities the mortality may be about 15 in the 1000, and the natives may live to the proverbial "age of a crow." Yet we cannot, on the strength of such cases, venture to assert that polluted waters are harmless and that their general use might be permitted with safety. Precisely similar is the case with the use of untreated sewage.

The pamphlet before us points out a way in which this particular danger may be obviated; and thus *one* at least of the many and formidable objections to the scheme of sewage irrigation may be removed. This has been done at Carlisle. The sewage of that town, before being allowed to flow upon the land, is mixed with carbolic acid, carbolate of lime, and sulphite of magnesia, as patented by Messrs. MacDougall. The disinfection is remarkably complete. No one who has visited the Carlisle farm complains of the "truly mephitic odours," such as the Prussian Commissioner, Lefeldt, laments at Romford, and such as everyone finds at Croydon. The crops, as stated in the pamphlet before us, are:—"Quite free from the rankness and liability to rot of all crops grown on sewage land where the antiseptic treatment is not adopted." Again: "It is also worthy of remark that,

whereas at other sewage farms parasites in the herbage are so abundant that many stock-owners object to pasture their animals on the irrigated meadows, the ravages of the parasites producing liver-rot and foot-rot being so greatly accelerated by the decomposing deposit on the land, at Carlisle the animals have been unusually free from these diseases." These statements are fully confirmed by information which we derive from other quarters. The stems of the grass grown on the Carlisle irrigation farm are not found filled to the height of some inches with unassimilated sewage-matter, nor do cattle, warned by their instincts, turn away from it with disgust. Neither, again, is the land watered with disinfected sewage haunted with those legions of flies and other noxious diptera which, in the vicinage of certain irrigation farms, constitute a perfect Egyptian plague, and which, first sucking up putrescent matters from the damp soil, and then biting the faces of the inhabitants, may at any moment transfer to them the infection of carbuncle, of ophthalmic, and of many other formidable diseases.

The expense of purifying sewage by this method is stated at one penny per thousand gallons, or £4 11s. 8d. per million. Thus, a town turning out 10,000,000 gallons of sewage daily, and disposed to adopt the irrigation principle, would incur for the disinfecting material an additional expense of, in round numbers, £1612 yearly. Against this would have to be set the superior quality of the produce raised, and the saving of stock which would otherwise perish from parasitical and entozoic disease. If sewage irrigation is to be tolerated at all—a point which, in our humble opinion, is by no means decided—it must be on the express condition of preliminary disinfection with the preparation recommended in this pamphlet, or with something analogous in its mode of action.

Our author appears, however, to have overlooked the obvious fact that carbolic acid preparations are by no means exclusively linked to irrigation. They may be, and actually have been, used with great advantage as adjuncts to other methods of treating sewage. When judiciously applied, they extinguish the life of germs and ova in sewage manures as well as in the effluent water. At the same time, unlike certain other disinfectants, they have in the proportions employed no injurious action upon plant life. Messrs. MacDougall were, we believe, the first to draw public attention to the germ-destroying power of the coal-tar products, and by so doing they commenced a new era in sanitary science.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Under this heading will be found an encyclopædic list of chemical papers published abroad during the past week, with abstracts of all susceptible of advantageous abridgment. The two half-yearly volumes of the CHEMICAL NEWS, with their copious indices, will, therefore, be equivalent to an English edition of the "Jahresberichte."

NOTE. All degrees of temperature are Centigrade, unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances de l'Académie des Sciences, September 8, 1873.

Fifth Note on Guano.—M. E. Chevreul.—The crystalline matter mentioned in the author's first note is, he believes, a neutral oxalate of ammonia. A fresh sample of guano, of a dull brown colour, and suspected of having been moistened, presented a curious fact. 100 grms. having been five times washed, each time with 100 grms. of water, and thrice more with 200 grms. of water each time, still gave an alkaline reaction. This phenomenon M. Chevreul ascribes to capillary attraction;

a force which he supposes to play an important part in agriculture, as regards soils and manures. In the aqueous extract he suspects the presence of one or more volatile and odoriferous acids, independent of avic acid. The bones of birds found mixed with the guano are reduced into irregular fragments, angular rather than rounded, of a brownish orange colour. These fragments have no cohesion, and if rubbed with a glass rod in a platinum capsule with a little water they are reduced to orange coloured flakes. The water becomes coloured, and on concentration it is found distinctly acid, and holds in solution an appreciable quantity of phosphate of lime.

Pyrogallol in Presence of Salts of Iron.—M. E. Jacquemin.—According to the author's experiments, ferrous sulphate never takes a permanent blue colour with pyrogallol except when it is partially peroxidised, as is shown by its being reddened by the alkaline sulphocyanides. Of the two he considers pyrogallol the more sensitive reagent for traces of ferric salts. In ferroso-ferric salts the blue colour turns first greenish and then red: 2 per cent of ferric salt is sufficient to produce this change in a few minutes. These red liquors become gradually turbid, and the next day a deposit of purpuro-galline may be separated by filtration. The filtrate on standing grows turbid again, and the second day a mixture of purpuro-galline and tanno-melanate of iron may be filtered off, but on the third day the tanno-melanate alone is formed. After the separation of the purpuro-galline traces of ammonia produce a deep blue-black, which becomes a fine purple-blue on dilution. If the quantity of ammonia is gradually increased the colour produced becomes a violet resembling that of anilin, an amethyst-violet, and a red. With syrupy perchloride of iron a concentrated solution of pyrogallol turns brown. If the solutions are dilute the blue colouration passes rapidly to red. The red obtained by the addition of an excess of ammonia is turned blue by acetic acid, and reddened again by an alkali. The author has likewise studied the behaviour of pyrogallol with ferric cyanide.

Reflections on Spontaneous Generation, in connection with a note by M. U. Gayon "On the Spontaneous Alteration of Eggs," and a note by Dr. Crace Calvert "On the power of Certain Substances to Prevent the Development of Protoplasmic Life."—A Béchamp.—The author states that there are at least three distinct albumenoid matters in the white of eggs; in the yolk, besides the microzymas insoluble in water, there are two bodies soluble in that liquid. He maintains that albumen, gelatin, infusion of yeast, with or without sugar, may be preserved easily in free contact with air. Urine and blood are easily preserved by creosote or phenol. Blood is one of the liquids where bacteria appear the least readily.

Researches on Crystalline Dissociation (continued); Evaluation and Distribution of Work in Saline Solutions.—MM. Favre and Valson.—When a salt is dissolved in water there is a contraction of the total volume of salt and solvent. But contraction can be produced in water differently, and without a salt, viz., by lowering the temperature. If we measure the number of calories yielded corresponding to a determinate contraction of water, we can estimate the corresponding mechanical work. In accordance with the mechanical theory of heat, if we measure the contractions of volume accompanying saline solutions we have a measure of the coercitive action of the salt on the water. This is the principle of the author's work. Having previously studied the solution of sulphate of soda (anhydrous and hydrate) on water, they here similarly study that of a number of other salts. They first determined the densities of normal solutions, or those containing uniformly 1 equivalent of the anhydrous salt (estimated in grms.) dissolved in 1 litre of water; and the densities of the salts. A table gives the densities of the salts considered in the anhydrous and in the hydrated states, and in the state of normal solution. It was

formerly found that a contraction of 1 c.c. in 1 litre of water at a temperature of 15° was equivalent to a liberation of 7576 calories; and that, conversely, this number of calories measures the work necessary to compress and diminish the volume of 1 litre of water 1 c.c. at that temperature. Hence, to obtain in calories the thermic effects corresponding to different contractions a , b ($a - b$), we have only to multiply these contractions by the constant number 7576. The numbers for the various salts are tabulated; and a third table gives the quantities of heat liberated or absorbed in the act of solution. It appears—(1) That the salts range in the following order of increasing contraction:—Borates, carbonates, sulphates, chlorides, acetates, bromides, iodides; (2) the contraction produced by solution of an anhydrous salt is greater than that of the same salt hydrated; (3) the contraction from solution of a hydrated salt is generally less than that produced in the formation of crystals; (4) the number of calories measuring the effects of contraction is much higher than the number of calories shown by the calorimeter; (5) the calories shown by the calorimeter have to be added or subtracted, according to their signs, from the calories deduced from contraction. As example of the second case, carbonate of soda (anhydrous) gives in dissolving a contraction of 21 c.c. corresponding to 15,096 calories, but there are 3658 calories set free, and shown by the calorimeter; the work of the solution is, then, represented by the difference, i.e., 115,438. (6) Anhydrous salts generally liberate heat in dissolving; hydrated salts generally give cold. All the salts examined liberate heat during their crystallisation.

New System of Representing Continuous Meteorological Observations, employed in the Algiers Observatory.—M. Buland.—(Note with memoir.)—The author advocates observing and recording the appearance of the sky, in addition to making meteorological observations with instruments. This not only gives more reliable results, but may lead to valuable inductions. He represents, in a graphic table, the hourly quantity of blue sky and of clouds (the various meteorological elements being also given). The sky is divided into ten equal parts; zero represents pure blue sky, or entire absence of clouds; 1, or ten-tenths, represents the sky covered with clouds. Three principal kinds of cloud (cirrus, cumulus, and nimbus) are represented by different colours. Thus, by simply inspecting the table, one sees how the cloudy periods succeeded each other, or how the periods of blue sky succeeded those of clouds. On comparing the various changes with the oscillations barometric, thermometric, anemometric, &c., one readily sees the connexion with these different meteorological elements. The author desires Government assistance in publishing 12 years' observations at Algiers, in addition to those now issued, which begin January, 1872.

Note on Magnetism.—(Continued.)—M. Gauguain.—Physicists find that in horse-shoe magnets the portative force increases with the time of contact of an armature. The author wished to know whether this increased magnetism would be shown by his method of induction-currents. He placed round one of the branches a loop of wire connected with a galvanometer, applied an armature of soft iron, and observed the current of demagnetisation; first, when magnet and armature had been in contact only a few seconds, and next, when the contact was prolonged several hours or days. The current was always the same, and the result is thus in discord with that above stated. M. Gauguain further determined the curve of demagnetisation of an electro-magnet; placing his wire loop successively at different points of the bar, and observing for each position the strength of induced current developed at the moment of interruption of the inducing current. The curve rises from the ends of the branches, reaches a maximum at a point covered by the bobbins, and then gradually falls to the heel. Thus its inclination changes sign four times throughout the length of the bar. Now

if one examines with a magnetised needle the magnetic state of an electro-magnet, one also finds that the magnetism changes sign four times. Starting from the boreal extremity, for example, the magnetism at the other side of the nearest bobbin is austral, it is zero at the centre of the bar, becomes boreal on approaching the second bobbin, and, finally, is austral beyond this bobbin at the end of the bar. This correlation is a striking one. In the case just described no armature was applied: where there is such, then, to obtain the curve of demagnetisation a new series of experiments have to be made. The loop being placed successively at various points of the bar, one determines for each point the value of the detachment-current (meaning by this the current induced when the armature is detached). By means of this curve, and the curve of demagnetisation obtained when no armature is applied, one may easily trace the curve of demagnetisation for the case in which the armature is applied. Studying this curve it appears that the increase of magnetism near the extremities on application of the armature is enormous; it may be 60 or 100 times the magnetism found before application. In the case of a permanent magnet the increase on application of an armature was not more than five or six times the previous magnetism. From this difference it results that if we compare an electro-magnet and an ordinary magnet by Coulomb's method of oscillations, and the method of weights carried, we should find by the former that the electro-magnet is weaker than the magnet, and by the second that the magnet is the weaker. These results are not in contradiction; the first method measuring the magnetic intensity which exists before the application of the armature, while the carried weight depends on the magnetic state produced after the armature is applied, and, as we have seen, the modification of magnetic state by the presence of an armature is very different in electro-magnets and in magnets.

Spontaneous Ascending Movement of Liquids in Capillary Tubes.—M. Decharme.—The author discusses the formula obtained from theoretical considerations based on experiment.

State of the Volcano of Nisiro in March, 1873.—M. Gorceix.—This island, one of the Sporades, is situated at the southern extremity of a line running N.E. and S.S.W., and nearly perpendicular to the volcanic axis of the Mediterranean. Several of the Sporades have experienced an increase of volcanic disturbance this year. Since historic times Nisiro has had no eruption with flow of lava till the month of March last.

Researches on the Spectrum of Chlorophyll.—M. Chautard.—This spectrum is characterised by a number of bands, one of which has the special properties of sensibility, sureness (in its division by alkalis, a character not found in the lines of any other organic liquid), and generality. Chlorophyll in plants exists in three different states, distinguishable through the spectrum—in leaves newly formed, in adult, and in dead leaves. In the first case, chlorhydric acid produces *accidental temporary* bands. In the second it produces quite another system of bands, which the author calls *accidental permanent*. In the third (and alcoholic solution) the accidental permanent bands appear immediately, without the intervention of hydrochloric acid. Chlorophyll is much less alterable than is generally supposed. It resists the action of iodine, acids, alkalis, digestive work; at least retaining characters by which it may be detected in mixtures the most complex and varied, and after lapse of considerable time.

New Observations on Presence of Magnesium at the Edge of the Sun; and a Reply to Some Points in M. Faye's Theory.—M. Tacchini.—The author gives observations, from June to end of August, of magnesium line, b , and the line 1474 $\text{\AA}$, the number of positions each day being noted. These vary from 26 to 60. August shows a maximum. The line 1474 $\text{\AA}$ is always found where the line b is found; but the reverse does not always

occur. Against M. Faye's theory the writer points out, among other things, that the penumbrae of spots are generally very broad, and many of their tongues, or currents, go to the very bottom in a way contrary to that which cyclones would show.

Employment of Chronometers at Sea.—M. de Magnac.—The writer describes observations on board the ship *Yean Bart*; they show that the application of Taylor's series, and of Cauchy's method of interpolation, to the daily working of chronometers gives great precision.

Les Mondes, Revue Hebdomadaire des Sciences, par L'Abbé Moigno, Tome xxxii., Nos. 3 and 4, September 18 and 25, 1873.

These numbers contain no chemical matter.

Berichte der Deutschen Chemischen Gesellschaft zu Berlin, September 3, 1873.

New Derivative of Valeral.—A. Borodin.—The author considers the compound which he obtained to be a polymer of valeral, having many points of resemblance to aldol. It undergoes a spontaneous change in course of time, and deposits crystals of the composition $C_{20}H_{42}O_5$.

Combinations of Bromal and Chloral with Benzol.—Guido Goldschmiedt.—The author has analysed and examined diphenyl-tribromæthan, $C_{14}H_{11}Br_3$; diphenyl-trichloræthan; diphenyl-dibromæthylen, $C_{14}H_{10}Br_2$; and diphenyl-dichloræthylen. He has further investigated the behaviour of hydriodic acid, and of sodium amalgam with diphenyl-tribromæthan, and that of zinc-powder with dephenyl-trichloræthan.

Chlorides of Molybdenum.—Dr. L. P. Liechti and Bernhard Kempe.—By the action of dry chlorine, perfectly free from air, the black pentachloride, $MoCl_5$, is obtained, which was formerly taken to be a tetrachloride. If this is reduced by hydrogen gas at the lowest possible temperature, e.g., 250° , the red, sparingly volatile trichloride, $MoCl_3$, is produced. This, if heated in carbonic acid free from oxygen, splits up into the yellow dichloride $MoCl_2$ which remains, and the brown tetrachloride, $MoCl_4$, which sublimes. The last mentioned compound was previously unknown. The atomic weight of molybdenum has been re-determined. Taking $O=15.96$; $Ag=107.66$; $Cl=35.37$; $S=31.98$; then $Mo=95.75$ to 95.94 , showing a mean value of 95.86 . The determination of Dumas was 95.65 ; and that of Debray 95.66 to 95.84 . The pentachloride is distinctly crystalline, and can be fused and volatilised without decomposition. On fusion it congeals to a black, radiating, crystalline mass. A green reflection shows the presence of oxychloride. The vapour is a deep brownish red. The sulphur-yellow dichloride and the red trichloride, which strongly resembles amorphous phosphorus, were only obtained amorphous. The tetrachloride appeared as indistinctly crystalline brown sublimes. The di- and trichlorides are perfectly stable in the air at common temperatures, and insoluble in water. The tetra- and pentachloride are easily affected by oxygen, and especially by moisture.

Existence and Dissociation of the Tetrachloride of Sulphur.—A. Michaelis and O. Schifferdecker.—The authors have isolated the tetrachloride of sulphur, and examined its dissociation, and that of the dichloride. The tetrachloride is composed of—

Chlorine	81.61
Sulphur	18.39

100.00

It is a mobile, brownish yellow liquid, quite distinct in colour from the red dichloride. When removed from the freezing mixture it boils up and loses chlorine.

Oxytetrachloride of Sulphur.—A. Michaelis and O. Schifferdecker.—The authors obtained and analysed this

substance to which they assign the formula $S_2O_3Cl_4$. Its composition is—

Sulphur	25.24
Chlorine	55.85
Oxygen	18.91

100.00

A white crystalline mass, closely resembling perchloride of phosphorus in appearance, of peculiar irritating odour.

Action of the Sulphite of Soda, and of Sulphurous Acid upon Iodide of Lead.—A. Michaelis and G. Koethe.—Iodide of lead can be completely transformed by sulphite of soda into sulphite of lead and iodide of sodium. Iodide of lead in the cold is only partially convertible by excess of sulphurous acid into sulphite of lead and free hydriodic acid. At higher temperatures the transformation is almost complete.

Direct Determination of the Constituents of the Carbon Compounds by Combustion.—A. Mitscherlich.—This paper is reserved for full insertion.

On Anilido-Acetonitril.—C. Engler.—This substance, to which the author assigns the formula—

is obtained by the action of anilin upon monochloro-acetonitril. It is a thick yellow oil, insoluble in water and dilute acids, but readily soluble in alcohol, ether, and concentrated acids.

Products of the Reduction of Acetophenon with Sodium Amalgam.—A. Emmerling and C. Engler.—The authors, correcting views they had previously entertained, state that a body which they described as a secondary ethyl-benzyl-alcohol is the pinakon of acetophenon.

On Propiophenon.—T. D. Barry.—The author has formed and examined crystalline nitro-propiophenon, $C_6H_4NO_2.CO.C_2H_5$; a syrupy nitro-propiophenon; amido-propiophenon, $C_6H_4NH_2.CO.C_2H_5$; and the secondary propyl-benzol-alcohol—

On Sulpho-Ortho-Toluidic Acid.—M. Limpricht.—This acid, $C_7H_8NSO_3H$, was obtained along with a more soluble isomer. Its potassium, sodium, barium, lead, and silver salts were examined. A bromated acid was formed, $C_7H_6Br_2NSO_3HH_2O$, and its salts were investigated.

Derivatives of Uric Acid.—E. Mulder.—The substances examined were the dialurate of urea—

(its aqueous solution gives a rich blue colour with sesquichloride of iron and ammonia), uroxanic acid, and alluranic acid. The latter, a new compound, has the formula $C_5N_4H_8O_4$. The author has also studied—Alloxan-silver; the reduction of alloxan and parabanic acid by hydriodic acid; the oxidation of mycomelinic acid; and the characteristic reactions of alloxantin and dialuric acid. Both give a blue colouration with ferric chloride and ammonia.

Action of Ammonia upon Bromacetyl-Urea.—E. Mulder.—If alcoholic ammonia acts upon bromacetyl-urea in a closed vessel in the water-bath, a colourless product is obtained, insoluble in alcohol. If it is treated with dilute hydrochloric acid, diglycol-amidate of di-uramid dissolves, and there remains a mixture of bromacetyl-urea and another body. From the mixture was obtained a body differing widely from diglycol-amidate of di-uramid in its properties, but not in its composition. The action of aqueous ammonia is different.

Chlorhydrate of Ethylen.—A. Ladenburg.—The author obtains aceto-chlorhydrin, $C_2H_4(OC_2H_3O)Cl$, by heating 1 part of chlorhydrate of ethylen with 14 parts of anhydrous acetic acid in a sealed tube.

THE CHEMICAL NEWS.

VOL. XXVIII. No. 125.

BRITISH ASSOCIATION FOR THE ADVANCEMENT
OF SCIENCE.

BRADFORD MEETING, 1873.

SECTION B.—CHEMICAL SCIENCE.

PRESIDENT, DR. W. J. RUSSELL, F.R.S.
(Continued from p. 186).

"The Bradford Sewage Works."—Mr. ANDREW LEIGHTON (London) gave a description of "The Bradford Sewage Filtration Works," in the course of which he said that it did not admit of a doubt that the purification of sewage, so that the effluent water could mingle innocuously with any stream, could be accomplished by the Peat Engineering and Sewage Filtration Company; but whether at a profit was an unsolved problem. Owing to the *vis inertia* of the farmers the sale of the manure was but slow, but the consumption was gradually growing. The principal reason of its sale being so backward was that its chief ingredient was charcoal, which bore no value in the analysis of the agricultural chemist, though the crops grown under the company's manure were the finest in England.

In the discussion which followed on the sewage question, Mr. STANFORD (Glasgow) said that with regard to the general report of the Sewage Committee, he had had the pleasure now of listening to it for several years in succession, and he was very glad to find that the gentlemen, in educating the country, were greatly educating themselves. They were at first, as Mr. Hope had happily expressed it, rather ill-connected, but they had been gradually picking up much better connections. First of all they were to have the country floated with sewage thrown over the fields just as it was, and now they were recommended to separate systems. He had pointed out some years ago that they must have a separate system for the sub-soil water, and one of pervious sewers for the drainage water. They were going now, instead of throwing the water over the land, to have it passed through the land. It was to be filtered, and it was also to be precipitated. All these were great improvements. He was extremely sorry, however, that the gentlemen who had formed the committee were now going to sit in their chairs and throw up any further trouble.

Mr. P. H. HOLLAND (Medical Inspector, London) said Mr. McGowen had very wisely directed their attention chiefly to the part of that very extensive subject in which he was best qualified to speak with authority, and which stood most in need of clear elucidation. Nearly all who had considered the question were well convinced that the proper destination of the very diluted manure called sewage was for the fertilisation of the land wherever land was accessible at a cost which could be repaid by the value of the manure, and, with a few exceptions, all were convinced that the objections urged against sewage irrigation, when properly applied, were either false or frivolous, very similar indeed to those often urged by those very intemperate arguers—advocates of temperance—who contended that because drinking to intoxication was injurious, therefore drinking without intoxication was so. By similar reasoning it was concluded that sewage irrigation properly done must be bad, because it would be if so used as to turn a pleasant meadow into a putrid swamp. Now this was exactly the difficulty. Some places were so situated that access to a considerable extent of land could not be obtained except at a cost out of all proportion to the profit to be expected, and until legal difficulties were removed such places were therefore compelled to run the risk either of converting a small area of land into a putrid swamp, or of spending a large amount that would never

be repaid, or of so far partially purifying the sewage that it might without offence be turned into the river, which was perhaps the best course to follow until the legal impediments to a better were removed. The local authorities were now liable to be forbidden by one injunction to turn foul water into a stream, and by another to divert any water from it, thereby diminishing its volume. Those using it for power claimed not merely its natural volume, but any addition that might have been artificially made to it. In the case of Bradford this artificial addition to the dry weather stream had been very considerable, 12,000,000 gallons being daily conveyed from the valley of the Wharfe to the Aire, and any quantity of sewage not exceeding that might be diverted from the Aire without reducing the stream below its natural volume; and no compensation ought to be paid unless the stream were diminished more than it had been artificially increased. Such a conservancy board as Mr. McGowen had proposed, with representatives of each interest affected, could be safely entrusted with larger and more varied discretionary powers than those representing ratepayers only. They should at least have powers throughout the whole of their district similar to those exercised by town councils within their boroughs; *e.g.*, they should be authorised to construct conduits wherever necessary for conveying sewage from the places where it was doing mischief to those where it could most conveniently be disposed of, without paying any other compensation than for land actually occupied, and for damage actually sustained. There need be no payment by a board having perpetual succession for possible prospective damage, as such board could at any time defray any legally-established claim. Such board should have power to purchase or hire by agreement any land suitable for irrigation, on condition that it was so used as not to be a nuisance. No one had a right to prevent another using his land in any way he pleased, merely because he imagined it might prove annoying. He must prove that it was so before he could prevent the land being so used; and it was very certain that the same quantity of manure put in the same land would be less, not more, annoying if it were mixed with a larger quantity of water, provided such water were not allowed to stagnate; and unless the manure were used in excessive and wasteful quantity, it need not be perceptibly offensive at all, and very rarely was so. Although he was not convinced that irrigation of land was the right mode for disposing of sewage, he quite expected that it would ultimately be resorted to for Bradford. He thought no one would doubt the wisdom of trying, as a temporary experiment at least, the possibility of so far purifying the sewage as to postpone the necessity for extensive works, which could not be effected without considerable change in the law; but the necessity of change of law had become so apparent that the representatives of large towns would find it indispensable to take common action, and insist upon such changes being made.

The LORD PROVOST of GLASGOW said he thought there were two things involved in this question. One was that different towns required different appliances; that one scheme would not do for every place, and that separate schemes were necessary for different towns. There was another conclusion which he thought they had all arrived at, and that was that the return, in a pecuniary point of view, was not likely to be satisfactory. There were one or two questions which he would like very much to ask, because he thought that the report from the general committee required their very greatest attention. He thought that there were some things in the report with which all parties would agree. One was that irrigation could be adopted with great advantage. Constituted as they were in Glasgow, they had in their neighbourhood a large extent of sandy soil, where the sewage could be removed, and in all probability give rise to a very considerable return of crop by being put there. It appeared to be the opinion of the engineers whom they had consulted that the removal of water carriage in that way would be very effective indeed. He quite agreed with the report of the committee that the

conservatism of sewage—that was, keeping it in the same place—must be condemned; at least he might say that, so far as they had found in all their experiments, they had not found one satisfactory plan by which they could recommend that to be put in operation. He would like to ascertain from the committee whether, in the consideration which they had given to the matter of irrigation, they included the chemical refuse in the sewage that they proposed to apply in the way of irrigation, or whether in the refuse of large towns the chemical ingredients would be as effective as if some process were taken to separate the one from the other; also, if they had made any calculation how much an acre of land would bear per annum of sewage; and whether they advocated intermittent sewage or a constant flow of sewage to be put on the same land.

Mr. B. LATHAM, in speaking of the report of the committee, said he did not think that such an association as that should issue dogmas which were not in accord with the experience of the country. One of the things they had been told was that the drainage must be carried out upon all irrigation grounds; but they had not been told in what way that drainage was to be carried out in order to secure the purification of the sewage. It was an important thing, and they all knew that drainage had a beneficial effect in irrigation on the soil, but in some cases it absolutely prevented the proper purification of the sewage. Where the surface of the soil was deep drainage was unnecessary, and where the surface was flat there drainage was absolutely necessary. With regard to the Bradford works, there was no one system which could apply to all parts. There were some cases in which dry conservancy must be carried out in conjunction with some system of drainage, but there was no way in which drainage in some form was not absolutely necessary.

Mr. HOPE (Chadwell Heath) said that as regarded drainage, if it was necessary in ordinary farm land, *a fortiori* it was necessary in clay land and in irrigation. If Mr. Latham was bound to take up his drains, it must be because they had not been properly put in. If they drained clay land they must drain it deeply. If they spent money upon the matter, they would get it properly done. He referred at length to the case of Birmingham, which recently came before Parliament, and of which, having himself been engaged in the proceedings on the bill, he was able to speak from personal knowledge of the details. With regard to the Aire and Calder Conservancy Bill, he did not know much about it, but he had heard that some land-owners were unkind enough to call it a bill founded by the wolf to protect the lamb in the stream. He was sure that no one could look at the town clerk of Bradford and say that he looked like a wolf. He would not admit that there was any town in the country which could not get land if they went to the expense. If there were towns on the upper branches of a river, the waters of which people wished or required to drink, then they must be made to purify their sewage at whatever cost. The cost was a secondary consideration, health being evidently the first. As to the London scheme, he might say that the Metropolitan Board of Works had no power at the present moment to deal with sewage.

Mr. BLAND suggested that it would be better if something could be found out by united efforts which would enable sewage to be efficiently precipitated and purified.

Dr. GILBERT said he understood the gentleman who spoke of the process now being adopted at Bradford to say that the whole of the manurial matters were retained. Without binding himself to any one particular figure, he would say that the sewage, as derived from domestic sources, would not contain more of its nitrogen than one-fourth on the average and even less; but, at any rate not more than one-fourth of it could possibly be precipitated from the liquid and retained in the manure. They had not been favoured with the results of any analysis of the deposited manure, and without those they could not form any definite opinion. With regard to the three-quarters

or more of the valuable matters and the putrescible matters which were left in the sewage after any such process as they had had described, the only way and the best way to purify that sewage was by irrigation if it could possibly be carried out. That was the only possible means and the only known means of its utilisation.

Mr. CHARLES ELCOCK (Manchester) hoped that the committee would not cease its labours at the present time. The whole question of the treatment of sewage was one almost as yet in its infancy.

Mr. STANFORD (Glasgow) proposed the reappointment of the committee.

Mr. MCGOWEN (Town Clerk of Bradford), in seconding the motion, said that the discussion which had taken place proved most satisfactorily and conclusively that if the committee which had been appointed to investigate this matter were to bring before the public anything thoroughly practicable and thoroughly useful, they ought to be reappointed again and again until they could arrive, not merely at some sound theories applicable to some districts, but at a good rule that should be applied to districts of special characters in different parts of the country. Mr. Hope had spoken of the land as easily to be obtained, but he ventured to assure him that it was not so. But Mr. Hope had said they might go 10 miles, and if they could not find it within 10 miles they might go 20. Now there was no magic in that, and therefore he would say that if they could not find it within 20 miles they might go 30. Now could there be anything more rash than such statements from any one coming into this part of the world, seeing how this part of the country was situated, its configuration, and the everlasting changes of altitude? Besides, had anybody ever contemplated the expense which would be the result of such a proposal being carried out? Mr. Hope had given them the most opposite illustration of all the difficulties which surrounded this question that he possibly could have selected. Referring to what Mr. Hope had stated in regard to the case of Birmingham, he said that when it was proposed to convey the sewage into a particular district, gentlemen were sure to say that it would depreciate their property. They might, if they chose to put it so, be as much mistaken in that as it was possible for a man to be mistaken, but he could not believe for a moment that a money object alone guided them. In such cases every man who had a piece of land to sell always declared it to be the best piece of land in the country. But let them look at what that led to. They could not get the land without going to Parliament. They applied for certain powers, and after acquiring the land and erecting the works, they might have a suit in Chancery about once every morning. He concluded by saying that he hoped the committee would look at the question in a serious point of view. The public would not have the streams polluted—let them avoid by all means recommending to enormous centres of industry, surrounded by tremendous difficulties, schemes that were very applicable indeed to sparse populations, but wholly inapplicable to such populations as these.

ON THE ESTIMATION OF CARBON IN PIG-IRONS.

By CHARLES H. PIESSE.

Most persons interested in the analysis of pig-irons have found that the process of filtering the separated carbon through a piece of combustion-tube narrowed at one end and partially plugged with asbestos, mentioned by Fresenius on page 573 of the third edition of his "Quantitative Analysis" (Bullock's translation) is anything but satisfactory. I have been using for several years a modification of that method which has the

advantage of allowing the operation to be rapidly completed. It is as follows:—

Place an accurately weighed quantity of about 3·5 grammes of the pig-iron (fine drillings) into a beaker, and pour upon it about 35 c. c. (10 c. c. for each 1 gramme) of a solution of cupric chloride, which has been made thus:—

Take of—

Cupric chloride	500 grms.
Sodium chloride (saturated solution)	900 c.c.
Hydrochloric acid (ordinary pure, sp.gr. 1·16) ..	50 c.c.
Distilled water	50 c.c.

Dissolve the cupric chloride in the solution of sodium chloride, and add the mixed acid and water. Filter the whole.

This solution should be quite transparent, and it is advisable to test it before use, by pouring some upon a sample of pig-iron known to contain a rather large quantity of combined carbon. Any evolution of hydrocarbons will indicate that the solution is too strongly acid. This only occurs when the cupric chloride contains a lot of free hydrochloric acid. It can be remedied by further drying the CuCl_2 over the water-bath, and making another batch of the solution, in which 50 c.c. of distilled water are substituted for the 50 c.c. of HCl , and then mixing the two batches.

The beaker containing the pig-iron and cupric solution is covered with a clock glass and allowed to stand for 2 or 3 hours in a warm place. By that time nearly the whole of the iron will have been dissolved, the carbon separated, and some metallic copper thrown down. The dark brown liquid produced (which consists of ferrous and cuprous chlorides) is to be very carefully decanted on to a filter directly to be described, a little more solution of CuCl_2 then added to the residue in the beaker, and that in its turn after standing a short time to be also filtered. This fresh addition of CuCl_2 to the residue and subsequent filtration to be made as long as any iron remains undissolved. Generally, however, two or three additions of the solution after the first are sufficient. It is advisable to keep the filter covered with a watch-glass between these successive filtrations to prevent the mass upon it from drying. The carbonaceous residue is then thrown on to the filter, and the beaker rinsed out with a saturated solution of NaCl , and cleaned by means of a cut quill in the usual way. The mass upon the filter is then to be thoroughly washed with the solution of NaCl until no iron or copper can be discovered in the filtrate on testing a few drops of it collected in a test-tube for the purpose, with K_4FeCy_6 and K_3FeCy_6 . The NaCl is then removed by washing with distilled water, and when nothing is left on evaporating 3 or 4 drops of this filtrate upon a platinum spatula, the washing is continued with boiling concentrated HCl (sp. gr. 1·16). This washing with HCl removes a quantity of iron, existing probably as hydrated ferric oxychloride from the unavoidable exposure of the ferrous chloride to the air. The iron being thoroughly removed by the hot HCl , that is now to be most perfectly washed out with boiling distilled water, and when every trace of it is gone, the carbonaceous mass is to be dried at 100°C .

The filter consists of a glass funnel into which a nearly circular slab of glass or porcelain* about $\frac{1}{4}$ inch in diameter has been so placed that it lies horizontally. The slab is covered with a layer of broken, nearly powdered asbestos, from $\frac{1}{4}$ to $\frac{1}{2}$ inch in thickness, that being well wetted with saturated solution of NaCl so as to sink it firmly together. A glance at the figure will render this description clear. A portion of the filtrate from every fresh decantation should be largely diluted with H_2O after adding a sufficiency of NaCl solution or HCl , to keep the CuCl_2 dissolved, and examined by transmitted light; if any particles of carbon are floating in it, the whole must be re-filtered, but if the filter has been properly made this will never happen. When the carbon on the filter is

perfectly dry, the funnel is to be inverted over a Wedgwood mortar containing some cupric oxide; the slab by being pushed from behind with a thick platinum wire falls with the asbestos and carbon on to the CuO in the mortar. The slab is then taken up with a pair of clean brass tongs, and should there be any carbon adhering to it (which but very rarely indeed happens) that is removed by rubbing it in the CuO , or by scraping it with a little clean asbestos. Attention is then turned to the funnel, to which nearly invariably some carbon adheres. This carbon is best removed by holding the funnel horizontally with one hand, and then putting a little CuO over a part of the carbon, covering that with some clean asbestos, and pressing on to it with a small platinum spatula, whilst revolving the funnel slowly, in its horizontal position; after one or two revolutions of the funnel the carbon will be entirely scraped off. To secure accuracy, this operation should be repeated twice or thrice. The position of the funnel, &c., is shown in Fig. 2.

FIG. 1.

FIG. 2.

The whole contents of the mortar are then thoroughly commingled by stirring with the pestle, the mixture being transferred to a combustion-tube in the ordinary way, and burnt in the style of an organic analysis. It is advisable to pass oxygen for about 10 minutes through the combustion-tube towards the end of the operation, to ensure complete oxidation of the graphitic carbon. By heating the mortar and CuO (which must of course have been previously heated to dull redness to expel moisture) in the water oven to 100°C ., this is prevented from absorbing moisture; but, nevertheless, a CaCl_2 tube should be interposed between the combustion-tube and the potash bulbs.

I need hardly add that by multiplying the weight of CO_2 found by 27·27, and dividing the product by the weight of the pig-iron used, the result will represent the percentage of carbon in the pig-iron.

ON THE ENERGIES OF THE IMPONDERABLES, WITH ESPECIAL REFERENCE TO THE MEASUREMENT AND UTILISATION OF THEM.*

By the Rev. ARTHUR RIGG, M.A.

(Continued from page 191).

GUNPOWDER has been introduced solely for the purpose of illustrating the questions that might arise in reference to the physicist's and chemist's views of affinity, and not for any purpose in reference to its use in mining or war.

If its introduction has made clear that the affinities amongst the atoms of which it is composed may be controlled, that the intensity and rate of its explosion (which is but another name for chemical combination) may be

* Easily made with pincers or champfers from a broken crucible-lid or glass plate.

* The Cantor Lectures, delivered before the Society of Arts.

regulated—that it and its related explosive agents may exercise their affinities without danger—harmlessly and slowly, then the inquiry is at once suggested, on what elements do chemical combinations depend? Why are these combinations accompanied with devastation and ruin. Why are they peaceful and unperceived?

Those who were present at the first lecture will be prepared for the suggestion that these differences arise (in part, at least) from some of those results which in that lecture were said to be deducible from a consideration of the units of time, mass, and space. Those fundamental units form a combination on which all our knowledge of work and production of energy depends. It will probably be remembered, too, that in the lectures on gravity and vitality these units of measurement formed the object of research by the men who have given to society the mode of estimating these energies.

It may have been noticed that whereas in the other lectures of this series the titles have in them the words, "especially with reference to the measurement of it," these words are changed in the title of the present lecture, and there are substituted for them the phrase, "especially with reference to considerations for measuring, &c." It will now be not inappropriate if one or two of the causes which lead to this difficulty in estimating the energies of affinity be made as clear as the competency of your lecturer will permit.
